SOME OBSERVATIONS ON THE TOXICITY OF SYNTHETIC ANTI-MALARIAL REMEDIES

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)
LIEUTENANT-COLONEL, I.M.S.
Professor of Pharmacology

and

R. N. CHAUDHURI, M.B. (Cal.)

Officiating Assistant Professor of Tropical Medicine
School of Tropical Medicine, Calcutta

DURING the last decade a large amount of work has been done on the chemotherapy of malaria; this has resulted in the production of several useful synthetic compounds. Of these plasmochin and atebirin are two well-known and effective drugs which are being extensively used by the profession, and the action of which is on a par with that of the cinchona alkaloids. Most of the anti-malarial remedies in use have their limitations and drawbacks. They may fail to control an attack of fever and more often they may fail to prevent relapses. The problem of the treatment of malaria and its complete cure is so important and urgent in this country that, in order to effect a cure, the medical profession in India have been trying various combinations of anti-malarial drugs. When plasmochin was introduced it was combined with cinchona alkaloids in different ways and extraordinary results were claimed for these combinations. There is no doubt that the two drugs together have certain advantages over administration separately. The main action of cinchona alkaloids is on the asexual forms and they generally control rapidly and effectively the symptoms of the disease. Plasmochin on the other hand acts chiefly on the sexual forms and has greater virtue in preventing the transmission of the disease to others by mosquitoes. The sexual forms are destroyed by this drug in a very short time and prolonged administration is not necessary. These facts have not been fully appreciated by the profession and one frequently meets cases where plasmochin in large doses by itself has been used in the treatment of malaria and to prevent relapses. In combination with cinchona alkaloids it has also been used for prolonged periods for similar purposes. Although a combination of cinchona alkaloids and plasmochin would seem to be ideal inasmuch as the one would destroy the asexual forms of the parasites and the other the sexual forms, there are serious disadvantages in this method of treatment. The cinchona alkaloids can be administered for prolonged periods without producing serious toxic effects, while plasmochin is a potent and toxic drug that does not bear repetition very often without

producing untoward effects, which may be serious.

Since the introduction of atebirin, the belief appears to be gaining ground in some quarters that a combination of the cinchona alkaloids with atebirin may be more effective. Both these drugs act mainly on the asexual forms and such a combination does not appear, so far as our experience goes, to increase their destructive power over these forms of the parasites. One does not increase the action of the other. A combination of plasmochin and atebirin would appear to be more rational and has been frequently used in this country. Many practitioners combine all three drugs and give them for prolonged periods. While the combination of atebirin and plasmochin may be theoretically sound and the most effective in the treatment and eradication of malaria, it appears to be toxic. We have recently seen a number of cases which have led us to form the impression that the toxicity of plasmochin is enhanced by combination with atebirin. While the data at our disposal at present are not sufficient to make a definite statement on this subject, it appears probable that there may be some truth in this opinion. The manufacturers, Messrs. Bayer-Meister Lucius, have also hinted at such a possibility in one of the leaflets issued by them and have deprecated the irrational combination of these drugs. A number of cases of poisoning with various combinations of these drugs have recently come to our notice and we have thought it desirable to record them so as to discourage irrational administration.

Case 1.—T., a European male, was admitted into the Carmichael Hospital for Tropical Diseases on the 12th September, 1933, for cyanosis and pain in the upper part of the chest and neck. Lately, he had several attacks of malaria which were at first treated with quinine. He was then put on plasmochin on the 4th September, 1933. On the first day (i.e., 4th) he had two tablets only. On the 5th, 6th, 7th and 8th he had six tablets each day of 0.02 gramme each and on the 9th two tablets. Cyanosis was first noticed on the 6th September, 1933, and three days later the patient had extreme prostration, headache, backache and epigastric pain. Cyanosis gradually deepened till it reached its maximum on the 9th September. Plasmochin was stopped and the symptoms, with the exception of cyanosis, rapidly disappeared. Physical examination showed no abnormality in the heart, lungs and kidneys. Fresh films of the blood showed well-marked enlargement of the red blood corpuscles and the colour was dichroic (yellow and green). On spectroscopic examination no band of methæmoglobin was seen. There was a trace of albumin in the urine.

Cases of this kind are very commonly met with and we have given one here as an example to show that some practitioners use plasmochin in the routine treatment of malaria in the same way as quinine. They employ fairly large doses, as much as 0.06 gramme daily, which is the maximum dose recommended and which in Indian patients, in our experience, usually produces toxic effects.

Case 2.—B., a European male, was admitted in December 1933 for periodical attacks of malaria since 1927. Shortly before his admission he was given three tablets of atebirin and 0.03 gramme of plasmochin daily for five days. As soon as this course was finished he developed pain under the lower part of the sternum and in the epigastric region and had difficulty in breathing. He also developed cyanosis of the lips and finger nails and suffered from severe palpitation. These symptoms continued with intensity for four or five days and then gradually abated. Clinical examination did not reveal anything abnormal except slight cyanosis of the lips. The blood count showed eosinophilia amounting to 15 per cent.

This patient had 0.03 gramme of plasmochin daily, a dose which usually does not produce toxic effects. In combination with atebirin however the toxicity of the drug appears to have been enhanced.

Case 3.—B., a Bengali doctor, was admitted on the 27th January, 1934, with symptoms of blackwater fever. He had been suffering from repeated attacks of malaria for about two years. Some months before his admission he himself took atebirin and plasmochin—one tablet of each three times daily for five days. Immediately on the completion of the course, that is on the fifth day, he experienced severe pain in the epigastric region which lasted for four or five days and then subsided spontaneously. He passed deep yellow-coloured urine at that time and his body turned yellow. The symptoms however cleared up within a few days. He was keeping fairly well when he suddenly got an attack of blackwater fever and came to our hospital. The patient on admission was anæmic and jaundiced. The spleen was moderately enlarged but no malarial parasites were found in the peripheral blood.

This is another case in which the combination of atebirin with plasmochin produced untoward effects. Whether the administration of these drugs had anything to do with the production of blackwater fever it is difficult to surmise.

Case 4.—D., a European male, was admitted on 2nd February, 1934, for recurrent attacks of malaria in spite of intensive anti-malarial treatment. From June to August 1933 he had taken 10 grains of quinine daily but more (20 to 25 grains daily) during the attacks of fever. In September, he was given two plasmochin pills and 10 grains of quinine daily for 21 days, i.e., 42 pills of plasmochin and 210 grains of quinine in three weeks. After the completion of this course he had a relapse of fever within one week. He started quinine again and continued it in doses of 10 grains daily until towards the end of last December when he had another relapse. This time he had taken a combined course of plasmochin, atebirin and quinine. This course lasted for five days and consisted of three tablets of atebirin, two of plasmochin and 10 grains of quinine daily. He took the full course without any discomfort, but a day after it was completed, i.e., on the seventh day, he was attacked with severe pain in the epigastric region along with incessant vomiting. The symptoms were very severe and intractable and the attending physician had to give him injections of morphine. After treatment for two days the symptoms subsided. He was sent to us for investigation. Physical examination showed slight enlargement of the spleen; the liver was normal. The heart was rapid and the sounds were weak, but no murmurs could be heard; the patient was anæmic but complained of no symptoms. No malarial parasites were found in the peripheral blood. Electrocardiographic examination of the heart showed it to be quite normal. With rest and hæmatinic drugs the patient rapidly improved.

This patient had a prolonged course of plasmochin and quinine without toxic effects but when these drugs were combined with atebirin, although the dose of plasmochin did not exceed 0.02 gramme daily, toxic symptoms supervened. This case also shows the futility of prolonged administration of anti-malarial drugs to prevent relapses.

Case 5.—G., an Anglo-Indian priest, was admitted on the 3rd of February, 1934, with a history of intermittent fever with rigor and vomiting for three days. He contracted malaria in October 1933 and since then he has had periodical attacks almost every fortnight. He took quinine mixture for a short time only. Then he started taking two tablets of atebirin and one of plasmochin every alternate day and this he had done for several months except on the days he had fever. The patient had no untoward symptom because he took the drugs at intervals and in small doses. Physical examination revealed slight enlargement of the spleen and liver. He was very anæmic and run down. Scanty malignant tertian rings were found in the blood.

This case shows the futility of the use of such drugs for an indefinite period for prophylactic purposes.

Case 6.—J., a European missionary lady, was admitted to the hospital on 4th April, 1934. She had an attack of malaria in the beginning of March last and was given atebirin and plasmochin two tablets of each a day alternating with one tablet of each a day. After taking these regularly for a fortnight, she was suddenly attacked with excruciating pain in the epigastrium and precordial region, associated with vomiting and cyanosis. These were at first regarded as symptoms of malaria, and she continued the drugs for another two days. As the symptoms grew worse, the drugs were subsequently stopped. Vomiting persisted for three days, cyanosis persisted for about a week and the pain persisted for eleven days. The patient was very weak, pale and anæmic. There was no enlargement of the spleen and liver. No parasites were found in the blood even by culture.

The symptoms in this patient are undoubtedly those of plasmochin poisoning, although the dose of the drug given was small.

Case 7.—X., a European male, came to the outpatient department in April last to learn the exact method of taking anti-malarial drugs for prophylaxis. He said that, while touring in Assam about a month before, he took atebirin and plasmochin to avoid malarial infection, but 'was nearly killed by them'. On the first day he took two tablets of each; on the third, fourth and fifth days he had three of each. On the sixth day he felt very depressed and had slight pain in the stomach. The pain was very severe on the seventh day and he felt as if he was going to die. It practically disappeared on the eighth day, but next day his whole body turned yellow; this however cleared up in a few days.

This is an example where a patient started the combined use of the two drugs as a prophylactic against malaria on his own initiative. Such cases are frequently met with in India.

Case 8.—G., a young boy of ten years, relative of a member of the staff of the Medical College, was brought to us in April last for persistent slow fever. His illness started with a high remittent type of fever; this persisted for about a fortnight and was followed by low fever for the last three weeks. The boy was in his native village and was being treated by the local doctor. At first he was given quinine (exact dose not ascertained) for four or five days, but as it had no

effect on the temperature he was given atebirin, one tablet thrice daily for four days, without any effect. Then (about the ninth or tenth day of his illness) he was put on plasmochin compound tablets, three times a day. After three days the boy was attacked with severe pain in the liver. This was apparently diagnosed as amoebic hepatitis, plasmochin was omitted and the patient was given an injection of half a grain of emetine hydrochloride by the medical man in charge. Next day he was given another $\frac{1}{2}$ grain of emetine by injection, but the pain in the liver as well as the fever persisted. On the following day he was given 1 grain of emetine hypodermically along with aristochin by mouth. The boy collapsed and his condition became very critical. He however revived with camphor injections and stimulants. The pain gradually subsided within a week but as the fever was persisting he was brought to us for advice. The patient was very pale, anemic and emaciated. The liver was enlarged $\frac{3}{4}$ inch below the costal margin, the spleen was not palpable. The heart was rapid (124 per minute) and the first sound was short and weak. The abdomen was slightly distended and the colon loaded. No malarial parasites were found in the blood. The total leucocyte count was 18,000 per c.mm. and the differential count showed 5 per cent myelocytes; there was a severe degree of anaemia of the microcytic type. As he was unwilling to come into hospital he was advised absolute rest in bed, regulation of the bowels, iron tonic and glucose. After a month the fever subsided, the leucocyte count was practically normal and the boy gradually recovered.

In this case the toxic effects produced by the anti-malarial drugs evidently were mistaken for dysenteric hepatitis and injections of emetine were irrationally given.

Case 9.—G., a Hindu female, was admitted into hospital on the 12th April, 1934, with a history of irregular fever for six months. She had been diagnosed as a case of kala-azar and given thirty-five antimony injections during the last few months, but the fever was not controlled. About a fortnight before her admission she was given tablets of atebirin and plasmochin each thrice daily. She took them for four days, after which she complained of severe palpitation and precordial distress. She was very pale, thin and anemic. The heart was slightly enlarged and there was a systolic bruit. The liver was $\frac{1}{2}$ inch and the spleen $2\frac{1}{2}$ inches below the costal margin.

Electrocardiogram report

P-R interval—0.12 second.

Heart rate—136 per minute, regular.

Voltage of R wave (lead II)—0.80 millivolt.

T wave absent in leads I and II and inverted in lead III.

This report indicates severe myocarditis.

Blood examination showed a leucopenia and a severe macrocytic type of anaemia. No malarial parasites were found. Serum tests were negative. The patient was treated with rest, digifortis, glucose and liver preparations, and gradually recovered.

Case 10.—S., an Anglo-Indian male, was admitted into hospital on the 15th August, 1934, for repeated attacks of malaria, general debility and pain in the right hypochondrium.

During October 1933 he contracted malaria and was given one full course of atebirin after which he turned pale yellow. As the spleen was still enlarged he was advised to take three tablets of plasmochin daily. After two days of this treatment he felt 'queer', but did not think much of it. On the third day he noticed a blue tint in his finger nails. Next morning he went to a place thirty miles away by train and soon after his arrival there he had pain in the liver region, and felt very ill. He took a dose of salts but this did not work well; that night he had fever associated with severe pain in the hepatic region, he vomited twice

and could not pass urine. He thought the whole trouble was due to malaria and continued taking plasmochin. The pain grew worse next day, his body became cyanosed and his general condition was serious. A medical man was called in who found the heart very weak and irregular and the patient in a collapsed condition. Plasmochin was stopped, stimulants were given and the toxic symptoms gradually subsided. The patient was sent to our hospital for treatment.

This case illustrates the development of yellow coloration after atebirin; and pain, vomiting, cyanosis, dysuria and cardiac irregularities after plasmochin. The toxic symptoms here appeared after administration of 0.06 gramme of plasmochin in two days. This is a small dose and it would appear that either the patient was particularly sensitive to the drug or more probably the previous administration of atebirin potentiated the toxic effects of plasmochin. This case also shows the great danger of allowing patients to take these drugs themselves.

Case 11.—L., a Hindu male, was admitted on the 24th August, 1934, for gastritis. In October 1933 he had an attack of malaria. For the first two weeks he had two tablets of atebirin daily, with a tablet of plasmochin half an hour after the atebirin. He was then advised to take one tablet of atebirin and plasmochin every third day for a fortnight; after that he had one tablet of each drug once a week for two weeks; thereafter he had a five-grain tablet of quinine once a week along with 'pyrex' thrice daily for two months. Ever since this treatment he has been getting pain in the stomach, indigestion and vomiting off and on and he came to us on this account. The patient was thoroughly examined and repeated protozoological and bacteriological examination of the stools gave negative results.

This is an example where both plasmochin and atebirin were prescribed at irregular intervals for prolonged periods. The medical adviser had no idea as to how the drugs should be used nor how they acted. A number of patients who have come under the authors' observation show that these drugs, if improperly used even in small doses, produce gastro-intestinal irritation, indigestion and vomiting.

Discussion.—Out of the eleven cases described above ten showed definite toxic manifestations. Of these ten, nine complained of epigastric pain, which is the commonest symptom of plasmochin poisoning. Cases 3, 7 and 10 had yellow staining of the body, which is produced by atebirin. Electrocardiographic tracings of cases 1 to 6 and 10 and 11 showed no definite abnormality, and that of case 9 showed evidence of severe myocarditis. This patient had marked cardiac symptoms and was admitted soon after the symptoms of poisoning appeared.

It has been shown that occasionally plasmochin, even in small doses, is liable to produce gastric pain or cyanosis or both. Sioli (1926) was the first to use plasmochin and he described pain in the liver region and some cyanosis as toxic manifestations of this drug. Fischer and Weise (1927) used plasmochin in the treatment of 172 cases of naturally-acquired

malaria and noted that such symptoms as cyanosis of the fingers, toes, lips and face were not uncommon, while spasmodic gastralgia occurred occasionally, especially when the drug was given on an empty stomach or in large individual doses. Schulemann and Menini (1927) treated 100 cases with plasmochin; it was reported that slight cyanosis of the lips and cardiac arrhythmia were common, while in three cases the cyanosis was of an alarming nature. A relative lymphocytosis and gastralgia were also noticed. The physicians of the United Fruit Company (1927) reported one fatal case in a Negro, the main histological finding being early central necrosis of the liver. Sinton and Bird (1928) had unsatisfactory results with pure plasmochin. In 22 out of 29 patients the course had to be interrupted owing to development of toxic symptoms; four patients failed to complete the course and two became dangerously ill.

Namikawa (1928) reported that in twenty-five cases of malaria treated with plasmochin nine suffered from toxic manifestations. Three benign tertian cases experienced pain in the hepatic region, tachycardia, high fever and cyanosis. Three subtertian cases had black-water-fever-like symptoms on the third to the sixth days, *i.e.*, jaundice, rigor, fever and hæmoglobinuria; the doses given were 0.06 gramme daily. Fischer and Weise found methæmoglobinæmia in ten out of thirteen patients on 0.03 gramme a day and in seven out of seventeen on 0.02 gramme a day.

Amy (1934) recorded some cases of plasmochin poisoning in Quetta. He also pointed out the relationship between such cases and black-water fever. The clinical and pathological characteristics are practically speaking indistinguishable from those of blackwater fever, except that:—

1. Oxyhæmoglobinæmia with oxyhæmoglobinuria is never a result of this form of poisoning, but occurs in blackwater fever.

2. So-called cyanosis is a feature of the poisoning, but it is absent in blackwater fever.

When it is noted that a patient is suffering from oxyhæmoglobinuria and that cyanosis is not present, a diagnosis of blackwater fever is probably correct. On the other hand, when the guide-posts are methæmoglobinuria and cyanosis, plasmochin toxicity suggests itself, to the exclusion of blackwater fever.

Atebrin is a much safer and more potent drug in the treatment of malaria than plasmochin. Green (1932 and 1934) gives an account of 50 cases treated with atebrin. 0.1 gramme per 15 kilogrammes body weight is the optimum daily dose. Two tablets of 0.1 gramme each every morning and one tablet every evening, continued for seven days, were given by him to persons with an average weight of 48 kilogrammes. The drug begins to appear in the urine on the third or fourth day after administration and

continues for more than a week after cessation of treatment. Yellow discoloration of the skin and eyes was noticed. Four patients complained of abdominal pain and two of headache. The drug appeared to have a cumulative effect.

Thonnard-Neumann (1931) treated 60 cases of malaria in Columbia with atebrin alone or combined with plasmochin. The doses employed were atebrin 0.1 gramme tablets thrice daily after food for five consecutive days and when plasmochin was administered it was given in doses of 0.01 gramme per dose. Yellow coloration of the skin which disappeared in two weeks was noticed in several cases. Abdominal pain was noticed only in cases treated with plasmochin in addition. Napier and his co-workers (1932) and Chopra and his co-workers (1933 and 1934) have used atebrin in over 200 cases of malaria in Calcutta without producing any serious toxic effects.

The toxic effects in the above-mentioned cases were chiefly produced by plasmochin and the simultaneous use of atebrin may have played a part later by increasing the toxicity of plasmochin or by making the patient sensitive to the latter drug.

Information regarding the causation of various symptoms is scanty. Several hypotheses have been advanced but none offers a satisfactory explanation. It has been suggested that symptoms are connected with a progressive accumulation of the drug or its by-products in one part, or system of the body. A little more information on this point has been obtained by Thonnard-Neumann (1931) and x-ray examination of the bowels (after combined atebrin and plasmochin) showed a 'hyper-peristaltic stomach', together with 'spastic contractions of the small and large bowel'. The effects may have been due either to atebrin or plasmochin acting separately, or possibly to some new product formed by the interaction of the two drugs in the body.

It should also be remembered, however, that some individuals are undoubtedly more sensitive to the drug than others. Toxic symptoms appear early and are generally more marked in those patients who are very weak, anæmic and run down. It would also appear that the toxicity of plasmochin is enhanced when combined with atebrin, at any rate in some of the cases, but this point requires further study.

Summary and conclusions

A number of instances of the toxic effects produced by the synthetic anti-malarial remedies have been given so as to impress on the profession that care should be exercised in the use of these drugs.

The main action of plasmochin is on the sexual forms and therefore it has neither very marked curative action in this disease nor does it prevent relapses.

The sexual parasites are destroyed by small doses after a few days' administration and therefore the main function of the drug is to prevent dissemination of the disease by mosquitoes.

Plasmochin is a toxic drug and does not bear repetition too often without producing serious toxic effects.

It has been shown that 0.02 grammes of plasmochin daily for a two or at most three-days' course causes disappearance of the crescents in the peripheral blood in cases of Indian strains of malaria and prolonged use is unnecessary and dangerous.

Neither plasmochin nor atebtrin should be used for prolonged periods for prophylactic purposes.

Patients should not be allowed to use these drugs except under direct medical supervision.

There is some evidence to show that combining atebtrin with plasmochin increases the toxicity of the latter.

ATEBRIN IN THE TREATMENT OF MALARIA IN RAILWAY EMPLOYEES

By C. D. NEWMAN, M.B., B.S., D.T.M. & H. (Eng.)
Chief Medical Officer, Eastern Bengal Railway
and

B. S. CHALAM, L.R.C.P. & S. (Edin.)
Malariologist, Eastern Bengal Railway

From the time of the discovery of cinchona up to 1926 when Professor Schulemann found a more effective anti-malarial remedy in a synthetic compound known as plasmochin, the only drugs that had been used effectively in the treatment of malarial fever were cinchona bark and the alkaloids obtained from it, particularly quinine.

Plasmochin had little therapeutic value in the treatment of subtertian malaria, having no action on the schizonts of *P. falciparum*, but it possessed the unique property of destroying the crescents or sexual forms. This drug had a certain value in the cure of benign tertian and quartan malaria and, to augment its curative effect, it became the practice to combine quinine with plasmochin in treating all types of malaria. Plasmochin, however, required medical supervision for its administration as it was found to be toxic and likely to give rise to severe untoward symptoms.

The introduction of atebtrin in 1929 by Schulemann and his collaborators marked a definite advance on the old and tried remedy, quinine, the newer preparation plasmochin and on the combined quinine and plasmochin treatment.

The treatment by atebtrin has been reported on by many workers to be short, simple, and effective. Such a treatment appeared to us to be most suitable for cases amongst the staff on a railway where the 'sick-man-days' lost to railway administrations due to malaria is such a burden, both financially and by loss of efficiency.

We are herein summarizing the results of a study of the effects of treatment of malaria by atebtrin and plasmochin on over 300 patients living under conditions that generally appertain to all Indian railways. In nearly all cases the patients were treated as outpatients.

The Eastern Bengal Railway traverses parts of Bengal where malaria is endemic, the cases ranging from the very mild to fulminating ones attended with fatal results. Our patients may therefore be taken to represent infection with many strains of parasites prevalent in Bengal.

The studies in this connection were undertaken mainly to determine:—

- (1) the best method of administration of the drug;
- (2) its effect on the parasites—sexual and asexual;
- (3) its effect on the temperature and other symptoms in malaria;

(4) its effect on the splenic enlargement and relapses;

(5) any untoward symptoms caused by its administration.

Grouping.—The patients were placed in the following three groups:—

- (1) Persons with parasites in the blood.
- (2) Persons with enlarged spleens and previous history of malaria, but with no parasites in the blood.
- (3) Persons with neither enlarged spleen nor parasites, but with definite previous history of malaria.

Administration of treatment.—Each group was further divided in two batches:—

(A) One batch was given atebirin only for the first five days and then plasmochin for the next five days; thus a period of ten days was required for the full course of treatment;

(B) the other batch was given atebirin and plasmochin together during the first five days; thus the period of treatment was reduced to only five days.

The dosage of these drugs was as follows:—

A. For those given atebirin for the first five days and plasmochin for the next five days.

Adults.—One tablet of atebirin ($1\frac{1}{2}$ grains) three times a day for the first five days, i.e., a daily dose of $4\frac{1}{2}$ grains.

One tablet of plasmochin ($1/6$ th grain) three times daily for the next five days, i.e., a daily dose of $\frac{1}{2}$ grain of plasmochin per day.

Children from 1 to 5 years.—One tablet of atebirin ($1\frac{1}{2}$ grains) in three divided doses per day for the first five days.

One tablet of plasmochin ($1/6$ th grain) in three divided doses per day for the next five days.

Children from 6 to 12 years.—One tablet of atebirin ($1\frac{1}{2}$ grains) twice daily per day for the first five days, making a total quantity of three grains of atebirin per day.

One tablet of plasmochin ($1/6$ th grain) twice daily per day making a total of $1/3$ rd grain of plasmochin per day.

B. For those given atebirin and plasmochin together during the five-day course.

Adults.—One tablet of atebirin ($1\frac{1}{2}$ grains) and one tablet of plasmochin ($1/6$ th grain) in the morning, a similar dose being repeated in the afternoon and evening. Thus each adult had three tablets of atebirin and three tablets of plasmochin per day, i.e., a total quantity of $4\frac{1}{2}$ grains of atebirin and $\frac{1}{2}$ grain of plasmochin.

Children from 1 to 5 years.—One-third of an atebirin tablet, i.e., $\frac{1}{2}$ grain, and one-third of a plasmochin tablet, i.e., $1/18$ th grain, in the morning, a similar dose being repeated in the afternoon and evening. Each child in this group therefore received $1\frac{1}{2}$ grains of atebirin and $1/6$ th grain of plasmochin per day.

Children from 6 to 12 years.—One tablet of atebirin ($1\frac{1}{2}$ grains) and one tablet of plasmochin ($1/6$ th grain) in the morning, a similar dose being repeated in the evening. Thus each child in this group received 3 grains of atebirin and $1/3$ rd grain of plasmochin per day.

Children over 12 years were given the same doses as adults. Children under 1 year were not given any atebirin or plasmochin and are not included in this report.

Methods adopted.—Atebrin was given by the mouth after food either in tablet or powder form. As it leaves no lasting bitter taste in the mouth, it is readily taken by children.

The observations recorded covered a period of eighteen months from January 1933 to June 1934 and include a total of 334 patients. The patients taken up for treatment underwent a thorough physical examination, the peripheral blood was examined and the number of parasites both sexual and asexual per cubic centimetre was determined. Careful daily parasite counts were made in one series of 17 cases. In the rest, the blood was examined before treatment, on the fourth day of treatment and after treatment. A special dispenser was deputed to see that the prescribed doses were swallowed in his presence and in no case were the drugs given to the patients to be taken in the absence of the dispenser. No other drug was given except a purgative, when necessary, and no restrictions regarding diet were observed.

As all the patients were railway employees or their dependents, living in the railway colonies, they were under close observation after the completion of the course of treatment and in a large number of cases it was possible to make fortnightly examinations of the blood after the end of treatment. Though plasmochin has its special value in destroying the gametocytes of subtertian malaria, we made it a rule to give both atebirin and plasmochin in all forms of malaria for reasons to be explained later.

Results of treatment.—In group I, there were 143 cases with positive parasite findings—118 subtertian, 14 quartan, 10 benign tertian, and one mixed subtertian and quartan; out of these, 114 were given atebirin and plasmochin separately (group I-A), while 29 others received atebirin and plasmochin together (group I-B).

A study of this group shows that cases of all three forms of malaria responded equally well. The temperature usually came down on the second or third day of treatment, and on the fifth day there was complete disappearance of the parasites from the peripheral blood. After the fourth day of administration of atebirin, rigors were seldom observed. Atebrin caused a gradual reduction in the number of asexual parasites though in some cases (in 4 out of 17 cases in which daily counts were made—of group I-A) the asexual forms increased on the second or third day before finally disappearing on the fifth day. Very little difference was noted in the temperature records whether the case was treated with atebirin alone, or in conjunction with plasmochin, as the temperature came down within 48 to 56 hours in every case, showing thereby that atebirin adversely affects the asexual forms of all species of malaria parasite equally well.

On the sexual forms, atebirin has a slower action. Gametocytes of benign tertian and quartan disappear much more quickly than subtertian, while those of subtertian persisted even on the fifth day (in three cases of group

I-A). In some cases of subtertian, the gametocytes had however disappeared on the second or third day. It is therefore possible that atebirin may have some delayed action on the gametocytes of subtertian as they were noted to disappear by the eighth day in the three cases in which they had persisted up to the fifth.

Of the 66 chronic cases with enlarged spleen and without parasites in the blood (group II), there was rapid and perceptible reduction in the size of the spleen in 56 cases. Most of the spleens of two and three fingers were reduced to practically normal size. In two cases of group II-A which had six- and five-finger spleens, respectively, these were reduced to normal size, but the decrease in size was more gradual in long-standing cases and the spleen did not decrease to its normal size. The remaining ten cases in this series of 66 showed no reduction in the spleen size.

In chronic cases, the action on the temperature curve is less marked than in acute ones.

Group III consists of cases diagnosed only clinically, i.e., there were neither parasites in the blood nor enlargement of the spleen, but there was a definite history of clinical malaria. These responded equally well to the treatment, the only noticeable difference being that in some cases the temperature persisted for a longer time than is usual in cases with positive parasite findings. It is probable that several of these clinical cases are chronic in nature, and as such the effect on the temperature was less marked than in acute cases with parasites.

Relapses.—On the Eastern Bengal Railway a relapse is considered as a return of febrile symptoms with parasites in the blood within a period of 12 months since the attack for which the treatment was undertaken. Although the figures, as far as the relapse rate is concerned, are obtained from the staffs of stations under malaria control, the control is not such as to absolutely exclude reinfection. Therefore the relapse rate figure is probably too high.

Of the 334 cases, 50 have 'relapsed' giving a 'relapse' rate of 14.9 per cent. Two cases in group I-A and one in group I-B relapsed within a month of the completion of treatment. All the patients who relapsed are from some of the most notoriously malarious places in Bengal, viz, the Dooars and Terai of Bengal. Some of the cases occurred in 'running' staffs, i.e., staffs not confined to one station, but engaged on travelling duties.

Though it is difficult to exclude the possibility of fresh infection, it should be noted, however, that the three cases of relapse cited above occurred within a month of the completion of treatment. Even granting that they may not be real relapses but fresh infections, such infection must have taken place before the atebirin had been fully excreted from the body, as the

drug can be detected in the urine up to 20 days or even longer. The data in our possession are yet too meagre at present to pronounce any definite opinion on the question of relapses after atebirin. We have this year instituted a systematic treatment with these drugs in the Calcutta Medical District of the Eastern Bengal Railway and are collecting statistics that might enable us to understand this aspect better.

It so happened that in November 1933 there was an accidental shortage of plasmochin and 22 cases (20 malignant tertian and 2 benign tertian not included in the series here reported) were treated with atebirin only. Curiously enough the two benign tertian cases have relapsed although none of the benign tertian cases of the 143 patients treated with atebirin in conjunction with plasmochin (group A) have relapsed so far. This suggests that even in benign tertian cases atebirin and plasmochin administration is better than giving atebirin alone. It is anticipated that the relapse rate will be still less with the two drugs than with one alone.

It may not be out of place to point out that although one can rely on a trained medical subordinate to spot a malarial parasite, such reliance cannot always be placed on his ability to spot the species of the parasite. On a railway system, patients are scattered, being at different places, and the identification of malarial parasites has perforce to be made by medical subordinates of varying grades of ability. In view of the fact that the inclusion or non-inclusion of plasmochin in the treatment depends on the correct identification of the subtertian parasites, and that there is a great possibility of errors in this direction, and in view of the probable decreased relapse rate in benign tertian cases if plasmochin is also given, there would seem to be sufficient justification for treating all cases of malaria with atebirin in conjunction with plasmochin, on railway systems at any rate.

Untoward and toxic symptoms.—Such symptoms when they occurred consisted of varying degrees of gastric pain, vomiting and yellow pigmentation of the skin. Of the 334 patients treated, 258 received atebirin and plasmochin separately, i.e., atebirin for the first five days followed by plasmochin for the next five days. Of these 258, fifteen cases exhibited the following symptoms:—

Five complained of slight pigmentation of skin.

Six complained of slight gastric pain.

One complained of moderately severe gastric pain.

Three complained of severe gastric pain and yellow pigmentation of skin.

None of these symptoms was of any consequence. The severe gastric pain complained of disappeared after a liberal dose of sodium bicarbonate with tincture of hyoscyamus. On the percentage basis it may thus be stated that 5.8 per cent of those treated with atebirin and

plasmochin separately exhibited untoward or toxic symptoms. The remaining 76 cases received atebirin and plasmochin together during the five days' course, i.e., atebirin and plasmochin were swallowed at the same time according to the dosage. In this series 16 persons, or 21.05 per cent, exhibited untoward symptoms. Of these one had extremely severe gastric pain, vomiting and slight collapse, while the others complained of gastric pain of moderate to slight intensity and pigmentation of the skin.

Pregnant women bear the drugs well. Persons exhibiting a high degree of idiosyncrasy to quinine can take these drugs without any discomfort. One patient could not tolerate a grain of quinine and was a constant sufferer from malaria; she was given atebirin and plasmochin together for five days more than a year ago, and ever since has been keeping well.

Cost of treatment.—The actual cost of one course of atebirin and plasmochin for an adult is Re. 1-11-8. As against this, the cost of one course of quinine treatment for three weeks is Re. 1-11-4½; but from the view-point of the saving in hospital costs, and reduction in the time lost by the patient, it is certainly a cheaper method of treatment than quinine.

Summary and conclusions

1. Atebrin and plasmochin are effective in the treatment of malaria due to all strains of plasmodium in Bengal.

2. It is uncommon to find a temperature above 99°F. after 48 hours' treatment.

3. With the exception of subtertian gametocytes it is rare to find malarial parasites in the blood after the third day of treatment.

4. In subtertian malaria plasmochin also should be given owing to its specific action on the subtertian gametocytes.

5. In the absence of absolute certainty regarding the species of parasite, it is beneficial to use atebirin with plasmochin in all forms of malaria.

6. Atebrin produces a rapid reduction in the size of the spleen.

7. People exhibiting idiosyncrasy to quinine tolerate atebirin with plasmochin well.

8. Atebrin given alone occasionally produces certain untoward symptoms which are seldom serious.

9. Atebrin and plasmochin given together cause untoward symptoms in a larger percentage of cases and the symptoms are more severe.

10. It is safer to give atebirin for the first five days followed by plasmochin for the next five days.

11. The cost of treatment is on the whole less than treatment with quinine.

NOTES ON AN EXPERIMENT ON THE PROPHYLACTIC AND CURATIVE VALUE OF ATEBRIN AND PLASMOCHIN THERAPY IN A TEA GARDEN IN ASSAM*

By D. P. WILLIAMS, M.A., M.R.C.S., L.R.C.P.

Chief Medical Officer, Assam Frontier Tea Company Limited, and Budla Beta Tea Company, Limited

and

RASAMAY BHATTACHARYYA, L.M.P. (Assam)
D.T.M. (Cal.)

Assistant Medical Officer, Bokpara Tea Estate
Doom Dooma, Assam

Introduction.—Malaria is a serious problem in all industrial concerns in India, especially in the tea industry. It is responsible for the loss of many working days, especially at a time when a tea garden can hardly afford it, not to speak of children's deaths, anæmia, loss of vitality and weakening of the power of resistance to other diseases. The necessity of malaria control is appreciated by all, but it is a very difficult problem to face. Moreover it is probably not realized by many that in order to form an accurate opinion regarding the practicability of permanent malaria control in any given locality, mature judgment, wide experience and a thorough knowledge of anti-malarial measures are required. Also the ability of the authorities concerned to provide large funds for it and the cost of maintaining it subsequent to its adoption have to be considered. Hence in many tea estates temporary anti-malarial measures are adopted of which drug prophylaxis is one. For about the last seven years plasmochin, and for about two years atebirin, have gained prominence in this respect and many papers have appeared as to the value of these drugs from various parts of the world with such varying results that we decided to make an experiment ourselves and form an opinion of our own as to the efficacy of these drugs as prophylactic and therapeutic agents in this locality. Bokpara Tea Estate of the Budla Beta Tea Company, Limited, was selected for this experiment and Colonel H. C. Garbett, C.I.E., V.D., superintendent of the company, kindly obtained the sanction of Rs. 1,000 for this purpose.

* Read at a meeting of the Assam Frontier and Budla Beta Medical Society held on 11th October, 1934.

(Continued from previous column)

The treatment of malaria with atebirin and plasmochin is a distinct advance. The treatment is simple, short and economical. The consistent use of this drug should effect a considerable reduction in the number of malaria cases and the consequent loss of working days due to this disease on Indian railways.

Description of the 'coolie line' where the experiment was conducted.—The experiment was carried out in one 'line' only, with a total population of 234, of whom 84 were men, 75 women and 75 children. The population was a stable one and there was no immigration of new labour into this line, not only during the season of experiment but for the last four years. There are 75 houses (of which 53 are 'pucca') in 10 rows running behind each other parallel to the 'pathar'—at distances from the 'pathar' varying from 25 yards, the nearest row, to about 200 yards, the row furthest away. There is a gradual slope from the houses down to the *bhil* which lies about 20 feet below the highest row and 10 feet below the lowest row. A sluggish stream flows into this *bhil* at the eastern corner of the line. This line is situated in the centre of the garden quite adjacent to the hospital but separated from two other neighbouring lines by a distance of quarter of a mile and one-eighth mile respectively. It has always been highly malarious and generally unhealthy. The inhabitants are mainly Oorials from Cuttack—a people notoriously liable to ills of all sorts and with a low resistance.

Methods adopted.—The experiment with atebirin and plasmochin was undertaken in 1933 from July to the end of the year with the following objects:—

(1) To determine the value of these drugs as a prophylactic in the method and doses given.

(2) To estimate their value as curative agents.

(3) To ascertain the toxic effects, if any, of these drugs arising out of the method adopted.

It was obvious that in dealing with a labour force on a tea estate it was quite impossible to administer any prophylactic drug three times a day; the administrative difficulties were insuperable and the dislocation of labour entailed by such an undertaking prohibitive. Besides it seemed to be inviting trouble to give atebirin three times a day quite irrespective of time and relationship to food, weather and work, even if such a thing were possible with the limited staff available. We were strengthened in this opinion by alarming reports from a tea estate on which such an experiment was attempted and had to be perforce abandoned quickly owing to the apparent alarming ill effects of atebirin and plasmochin on the labour. This was to be expected with atebirin given somewhat indiscriminately as noted above. Consequently it was decided to administer atebirin in one dose daily in the evening after work was over at the time of the taking of the evening meal. This was possible on this estate as the line on which the experiment was carried out was contiguous to the hospital. It was felt that if atebirin was to be given to a labour force as a prophylactic, unless it could be given in one dose with food, it was doomed to failure

owing not only to untoward effects* of the drug, but also to the dislocation of labour and the lack of time of the medical staff available. It consequently had to be determined in what dosage the drug could be given in one dose to be of any prophylactic value and at the same time to avoid accidents. The writers determined on the following single doses of atebirin and the following course:—

Adult men and women (those over 8 years were counted as adults) were given 2 tablets, or 3 grains in one dose per day after food in the evening.

Children between 4 to 8 years were given 2 grains in one dose per day after food in the evening.

Children between 1 to 4 years were given 1 grain in one dose per day after food in the evening.

Children under 1 year were given half grain in one dose per day after food in the evening. (The great majority of these children were breast-fed).

Those old enough to swallow were given the drug in tablet form; those too young in liquid form or rather in suspension in water. The administration was carried out by the junior writer and his staff in the evening between 6 and 7 o'clock. We can guarantee that the administration of these drugs was carried out properly in the manner indicated. It was decided to adopt the following procedure:—

Beginning on 17th July atebirin was given to the labour of the selected line to the number of 234 for five days, once daily in the evening after food in the doses already outlined. This was followed by plasmochin for five days, once daily in the evening after food in the following doses—

Adults were given one-third grain in one dose per day after food in the evening.

Children between 4 to 8 years were given a quarter grain in one dose per day.

Children between 1 to 4 years were given one-sixth grain in one dose per day.

Children under 1 year were given one-twelfth grain in one dose per day.

[Plasmochin tablets are available in two forms, viz, (i) .01 gramme or one-sixth grain and (ii) .02 gramme or one-third grain. The latter is grooved in the middle and can be easily divided into two equal parts.]

This was followed by plasmochin in the above method and dosage given twice a week till the end of November. In addition a second course of atebirin was given to the children only, for five days in the doses already outlined, beginning on 28th August and ending on 1st September.

The line population was seen by the junior writer every night till the end of September to detect any malarial cases or relapses and also

* We think it only fair to state that at the time when this experiment was begun the reported ill effects of atebirin were in all probability not due to atebirin at all, as such, but to its combination with plasmochin or the administration of it immediately following on atebirin before the latter is eliminated from the system. Our most recent experience inclines us to the opinion that the toxic effects of atebirin alone in the usual doses are negligible except for the yellow discoloration that shows itself occasionally.

to find out if there were any ill effects of the drugs. Blood slides of febrile cases (thick and thin films combined, stained by Giemsa's method) were examined for malaria parasites by the junior writer, and also some slides of children taken at random during the afebrile period. This daily work was continued by his successor Dr. D. C. Sen during October, November and December. All cases of malaria either primary after the first taking of these drugs or after a relapse were admitted to the hospital and given a five-day course of atabrin followed by a five-day course of plasmochin in the dosage and method shown in table I.

the longest period being 103 days and the shortest eight days. Cent per cent of this series relapsed; two of them (both Indians) relapsed twice.

It will be noted from table II that relapse rates vary according to age groups from 153.3 per cent in those below two years to 4.31 per cent in those over 15 years, showing the absence of resistance in the very young and gradual development of relative immunity in later age groups. The total average relapse rate for all ages was 21.36 per cent. The total number of relapses was 50 out of 234 for the five months, August to December inclusive. It may be

TABLE I

Age	ATEBRIN		PLASMOCHIN	
	Duration of treatment	Dose	Duration of treatment	Dose
Adults	5 days	1½ grs. thrice daily after food.	5 days	½ gr. thrice daily after food.
Children between 4—8 years.	Do.	1½ grs. twice daily after food.	Do.	½ gr. twice daily after food.
Children between 1—4 years.	Do.	1½ grs. once daily after food	Do.	½ gr. once daily after food.
Children under 1 year	Do.	¼ gr. once daily after breast feed.	Do.	¼ gr. once daily after breast feed.

Table II gives the relapse* rate by ages.

On an average the relapse took place 41.3 days after the completion of the course of atabrin, the longest period being 116 days and the shortest one day.

contrasted with the average number of relapses (on the same population during the same months) for the preceding five years which was 40.2. At first sight it occurs to one that atabrin and plasmochin had a provocative effect on

TABLE II
Showing relapses by ages

Four relapses .. .	1	1
Total relapses ..	23	10	3	4	4	6	50
Percentages	153.3	34.48	15	36.36	20	4.31	21.36

In another series of 12 private patients (all adults)—6 Europeans and 6 higher-class Indians—treated by the senior writer, relapse took place after 38.7 days counting from initial pyrexia,

* All malaria cases occurring after the administration of the drugs are counted as relapse owing to the intensity of the infection in this line especially in little children from the age of two months onwards.

the relapse rate. But it may be pointed out that during this experiment we always kept a very vigilant eye on this line and all cases of malaria were detected and admitted into hospital without exception, but in other years doubtless many cases, especially very young children, escaped notice and were left untreated in the line. Allowance must be made for this.

But at the same time it is evident that the treatment had no marked controlling influence on the relapse rate in children.

It will not be out of place to mention in this connection that between June and December 1932 inclusive, the junior writer carried out an experiment in the same line to test the prophylactic value of cinchona febrifuge in children alone, who are the main reservoirs of infection. He divided the line into two halves in a crosswise manner and daily gave cinchona excepting Sundays to 34 children of half the line. Forty-five children of the other half were left as controls without any treatment. He found the relapse rate in the former group as 64.70 per cent and in the latter group as 66.66 per cent. As the number is small no definite conclusion can be made but it suggests the failure of cinchona as a prophylactic in children. It is however possible that some of the relapses might be reinfections.

This table brings out clearly that as the treatment continued (i) relapses due to malignant tertian parasites progressively diminished; (ii) there was no progressive reduction in relapses due to benign tertian parasites.

Table V shows the monthly incidence of malarial infection in apparently healthy children whose blood slides were taken at random.

This table shows that as the treatment continued (i) malignant tertian infection was reduced, (ii) benign tertian infection persisted, and (iii) total infection gradually diminished.

Therapeutic results of atebirin and plasmochin treatment.—It has already been mentioned that the cases that relapsed were admitted into hospital and given a full course of treatment with atebirin and plasmochin, that is five days' atebirin followed by five days' plasmochin in doses outlined in table I. Fifty cases were thus treated, 10 cases being adults and 40 children. Routine parasitological examination was made only on admission and discharge. On

TABLE III
Showing parasitic incidence of the relapse cases

B. T.	M. T.	Quartan	Mixed B. T. and M. T.	Unclassified	Parasites not found	Total
17	13	1	4	4	11	50

This table shows (i) that relapses were higher with benign tertian than with malignant tertian and (ii) that benign tertian and malignant tertian infections were the predominating ones.

The months of incidence of benign tertian and malignant tertian parasites are shown in table IV.

TABLE IV
Showing the months of incidence

Months	B. T.	M. T.	Total
August ..	2	4	6
September ..	4	6	10
October ..	5	2	7
November ..	4	1	5
December ..	2	..	2
Total ..	17	13	30

discharge all were negative to malaria parasites; the result of examination on admission has already been shown in table III. It is unfortunate that for want of time the blood of each patient could not be examined daily nor could a comparative study be made with quinine. Temperature finally came down to normal after 2.7 days of atebirin, the amount of atebirin taken being according to age.

The idea underlying the giving of plasmochin was not of course to control symptoms, but to prevent infection in others. As already mentioned, the blood of all patients was examined on completion of plasmochin treatment but crescents were not encountered in a single case, which shows its efficacy as a crescenticide in the dose and length of treatment adopted.

Failures of atebirin therapy.—In one case atebirin failed altogether to control temperature.

TABLE V

Months	Total number examined	NUMBER FOUND POSITIVE					Percentage
		B. T.	M. T.	B. T. and M. T.	Unclassified	Total

Total ..	76	10	3	3	5	21	27.6

Another case resisted combined administration of atebtrin (by mouth) and quinine (by injection). Two other cases showed a rise of temperature on the day following the completion of the atebtrin course.

Toxic effects arising out of atebtrin and plasmochin treatment.—Yellow discoloration of the skin and eyes was noticed in three cases after the taking of 12 grains of atebtrin; this lasted about a week. One patient complained of diarrhoea after taking $7\frac{1}{2}$ grains of atebtrin—in this case it is difficult to say if the diarrhoea was due to atebtrin or was merely a coincidence. This however did not necessitate stoppage of atebtrin. One patient complained of anorexia after 12 grains of atebtrin, one patient complained of slight abdominal pain after 18 grains of atebtrin. three patients complained of giddiness, two after 12 grains and one after 9 grains of atebtrin. Abdominal pain was complained of by two patients during plasmochin treatment. It may have been due to plasmochin, but was more probably due to its combination with atebtrin that had accumulated in the system. Abdominal pain was relieved by temporarily stopping the drug, using aperients and milk diet.

It will be interesting to mention in this connection that two of the senior writer's private cases developed blackwater fever just after the completion of treatment with atebtrin and plasmochin given consecutively. Short notes of these cases are given below :—

Case 1.—Hindu male, aged 28 years, Bengali, compounder, had been suffering from malarial fever off and on for six or seven months. He experienced the last attack of fever on the 4th October, 1933. The blood slide was negative to malaria parasites. Two injections of quinine bihydrochloride gr. x each were given intramuscularly on successive days and the fever stopped. From the 6th to 10th October he was put on atebtrin one tablet thrice daily. From the 11th to the 15th October he was put on plasmochin one tablet ($\frac{1}{6}$ grain) thrice daily and on the 16th October he developed blackwater fever.

Case 2.—Hindu male, aged 40 years, Bengali, compounder, had been suffering from low fever in the evening for a month and a half, temperature never exceeding 99.4°F . On the 3rd December, 1933, his blood slide showed scanty malignant tertian rings. He had the last attack of fever on the 10th December, 1933. His blood slide was found negative for malaria parasites. Slides were then examined every day till the 20th December and were all negative. From the 10th December, 1933, he was put on atebtrin one tablet thrice daily for five days. From the 15th December he was put on plasmochin one tablet ($\frac{1}{6}$ grain) thrice daily for three days and the next day he developed blackwater fever.

It is significant that all the ill effects mentioned were observed in adults. This suggests that children probably bear these drugs better than the adults.

Contraindications.—We found no contraindications in the administration of these drugs. It is interesting to mention here that one adult female was admitted into hospital with high fever and intense jaundice. She was put

on atebtrin one tablet thrice daily for five days. Temperature finally came down to normal on the fourth day and jaundice disappeared in a further ten days' time. This suggests that malarial jaundice is not a contraindication to the administration of atebtrin. Four pregnant women who underwent the treatment tolerated the drugs well.

Relative cost of quinine and atebtrin.—The cost of a curative course of atebtrin (three tablets daily for five days) is Rs. 2-2. For an adult Indian patient of average health a curative course of quinine (twenty grains daily for seven days) costs annas 8 only. If we consider the relapse-preventing capacity of both the drugs the same, then quinine is decidedly much cheaper than atebtrin.

Summary and conclusions

1. The high incidence of malaria in a 'coolie line' in a tea garden in Assam gave an opportunity to carry out an experiment with atebtrin and plasmochin as to the efficacy of these drugs as prophylactic and therapeutic agents.

2. Two hundred and thirty-four people—159 adults (children over eight years were counted as adults) and 75 children were treated.

3. Prophylactic doses of atebtrin and plasmochin were distributed among the line population in the dosage and by the method described.

4. Those who developed fever were admitted into hospital and given a full course of treatment with atebtrin and plasmochin in the dosage and manner shown in table I.

5. There were 50 relapses* (21.36 per cent)—the vast majority of which were confined to the children population especially among those below two years of age, showing the absence of immunity in them. Of this age group, 11 cases had one relapse, 8 cases two, 3 cases three, and 1 case as many as four relapses.

6. The total infection and total incidence of malaria diminished to some extent; this diminution was due chiefly to the reduction of malignant tertian cases but there was no reduction either in infection or in incidence in benign tertian cases. But even this reduction of incidence in malignant tertian infections was not sufficiently satisfactory to compensate for the expense incurred.

* We consider that the use of the word *relapse* in this connection is misleading. When a patient is transferred to a malaria-free area for treatment, or is treated at a time of year when transmission is not occurring, then it is permissible to refer to a malarial attack as a *relapse*, but, in a highly malarious locality at a time of year when conditions are optimum for transmission, it is scarcely permissible to refer to *any* attack, unless it follows within a few days of the conclusion of treatment for the previous attack, as a relapse, and certainly not to refer to the thirty-five primary attacks—that is to say, primary as far as the experiment was concerned—as relapses, just because the patients had received a course of treatment for an infection which there is no evidence that they ever had, as these writers have done.—EDITOR, I. M. G.

7. The real value of an anti-malarial drug especially as a prophylactic agent can be gauged properly only when its efficacy is proved in terms of children and from this standpoint atebirin and plasmochin have failed, in our experiment, to fulfil the somewhat exaggerated claims made on their behalf. They have, however, decidedly better prophylactic value in adults.

8. We have not been able to determine the efficacy of atebirin relative to that of quinine but it is our impression that as a therapeutic agent atebirin is at least as efficacious as quinine in controlling the clinical symptoms and freeing the peripheral blood of malaria parasites.

9. On the point of toxicity atebirin is decidedly superior to quinine. It does not give rise to neurotrophic symptoms, is well tolerated by children and also those who have an idiosyncrasy to quinine as well as by pregnant women.

10. Ill effects are attributed to the combination of atebirin and plasmochin. In the method and dosage we followed, ill effects were very few and not at all dangerous.

11. The cost of a course of atebirin treatment is much higher than that of quinine but this higher cost is somewhat compensated for by the absence of neurotrophic symptoms. Therefore atebirin is a more suitable drug for those who can afford it but it cannot replace quinine in general use in a poor country like India.

12. Though it cannot be said with certainty that atebirin is a more effective therapeutic drug than quinine, it is undoubtedly a new anti-malarial weapon with some advantages over quinine and being, we hope, the precursor of more potent synthetic preparations has certainly opened up a new path for combating malaria.

13. As a gametocyticide plasmochin should be used in mass treatment, only under proper medical supervision and under suitable conditions.

14. In these days of economic depression, quinine will, in a tea garden, hold its present position till a cheaper and equally or more efficacious remedy is available.

15. We hold a very strong view that the published reports of atebirin and plasmochin treatment as prophylactics lose most of their value unless the age groups of the people so treated are given as well as the average length of time such people have resided in that locality.

Acknowledgments

We are indebted to the directors of the Budla Beta Tea Company, Limited, for sanctioning Rs. 1,000 towards defraying the cost of this experiment and to Colonel H. C. Garbett, C.I.E., V.O., superintendent of the company, for his good offices in obtaining this grant and for his interest and practical help. Our thanks are also due to Mr. H. O. J. Maxwell, manager,

Bokpara Tea Estate, for his co-operation and sympathy in the same and to Dr. D. C. Sen, L.M.F., who was responsible for the completion of the latter part of the experiment.

[During the last few years there has been, both in these columns and elsewhere, a considerable amount of discussion on the use of plasmochin by the sanitarian in an anti-malarial campaign. Experiments have been undertaken and reported; both successes and failures have been claimed—our use of the word *claimed* in connection with the failures is deliberate, as in most instances the writers have adopted an I-told-you-so tone in reporting these—but as a rule the discussions have not risen above the theoretical level. The theoretical case is perfectly clear; malaria, despite its name, is not born of the air and, therefore, if you can clear the population of gametocyte carriers, you must necessarily stop the malaria. Again plasmochin is a drug that will destroy with certainty all the gametocytes in any person to whom it is given in adequate doses. The point over which there is a disagreement of opinion is as to whether the facts that we know about plasmochin can ever be translated into practical politics, and, if the answer is in the affirmative, what are the special circumstances in which this can be done?

Conditions under which malaria exists and has to be controlled are so diverse that a very large number of experiments will have to be carried out to settle these questions; practical experiments, like this one carried out by Dr. Williams and his assistants, are therefore particularly welcome.

The writers have stated that the first object of their enquiry was 'to determine the value of these drugs [atebirin and plasmochin] as a prophylactic in the methods and doses given'. There are two aspects of prophylaxis—personal prophylaxis and general prophylaxis: the object of the former is to protect the person to whom the drug is given from an attack of malaria, of the latter to destroy the gametocytes circulating in his blood so that the general population is protected. There is no drug known to-day that will with any degree of certainty protect a person from malarial infection; neither atebirin nor plasmochin will effect this, even if given in large doses over long periods. However, both drugs given in adequate doses are capable of keeping the malarial infection at a sub-clinical level, as long as their administration is continued, and eventually of killing out the infection in some cases, but in these circumstances they are not acting as prophylactic but as curative drugs.

Dr. Williams gave a single sub-optimal course of atebirin and plasmochin in the middle of the malaria season followed by a single dose of plasmochin twice a week throughout the rest of the season. Even the extremists amongst those who have made 'the somewhat exaggerated claims', to which these writers refer, have never claimed that such a course could possibly protect the recipients from a malarial infection, or even keep the infection at a sub-clinical level beyond the few days during which the atebirin was being taken; we cannot therefore believe that it was personal prophylaxis that Dr. Williams hoped to achieve.

On the other hand this course might be expected to keep the population of the 'line' free from gametocytes (we are not told whether it did or not), and the scheme might therefore have been useful as a general prophylactic measure. The success of this would however depend entirely on whether this 'line' was an isolated one, sufficiently far from other human habitations to ensure that mosquitoes were not getting infected from other sources but we are told that it was adjacent to the hospital and two hundred yards from another line.

One thing that this enquiry has brought out very clearly is the imperative necessity of maintaining a

THE INSPECTIONAL VALUE OF PHRYNODERMA AND 'SORE MOUTH'

By LUCIUS NICHOLLS, M.D., B.C., B.A. (Cantab.)
Director of the Bacteriological Institute, Ceylon

MALNUTRITION may be considered to be due either to disease or to dietary deficiencies. When it is due to the former it may require a long and thorough inspection to find the cause. But the medical inspection of groups of persons such as school children, gangs of labourers constructing railways or other public works, employees in factories, or convicts in jail, is often required to decide the adequacy or otherwise of their diets.

Conclusions from these inspections have been based to a large extent on general appearances. When an individual shows adequate subcutaneous fat, firm muscles, a shining skin, clear eyes, a bright unworried expression and an alert gait, he has been well fed. But when an individual is very thin, or fat and flabby, without muscular tone, has a dry and rough skin, and an appearance of fatigue or hyper-irritability, he is ill fed or diseased.

Not only are there many degrees between these extremes, but a well-fed and healthy person may be thin and not alert, and an improperly-fed person may have ample adipose tissue and retain muscular tone.

Consequently it is difficult to give sound judgment from general appearances, and the conclusions of one inspector may be at variance with those of another; and slack and casual inspection is likely to be the result where the conclusions are made from indefinite signs.

Attempts have been made to determine the state of nutrition of school children by measuring and weighing them, and comparing their heights and weights with those given in standard tables. This method has been far from successful because some children are naturally tall and thin and others are short and stout. It is much better to use the measure and the scales at frequent intervals, and judge from gains or losses, but this requires time and is not always practicable.

Therefore any definite signs, or even symptoms, which are due to dietary deficiencies, will be of great value for the inspections of groups of persons.

In two recent papers (1933 and 1934) I have discussed the prevalence of two signs of dietary

deficiency namely phrynoderma and 'sore mouth' among school children, prisoners, and others in Ceylon. The former sign is due undoubtedly to vitamin-A deficiency, and probably the latter also is due to this deficiency, although there may be other factors. It is not surprising that the poorest classes of the teeming East should fail to obtain a sufficient quantity of vitamin A in seasons when green vegetables are scarce, because they cannot afford comestibles of animal origin which contain this vitamin.

The great value of these two signs for medical inspections has become well established in Ceylon, and are of special importance to school-inspecting medical officers.

The following four examples, selected from among others, will serve to illustrate this:—

Example I.—In an inland town there is situated a well-built school run by missionaries, and they receive and teach four classes of children—(1) orphans who are boarded; (2) day scholars of the poorest classes who are taught in the vernacular; (3) boarders who pay fees and are educated in English; and (4) day scholars who pay fees.

The orphans live apart from the paying boarders and receive a much inferior diet.

Table I shows the results of the inspection:—

TABLE I

	Number examined	SHOWING PHRYNODERMA		SHOWING 'SORE MOUTH'	
		Number	Per cent	Number	Per cent
Day paying scholars	58	5	8.6	8	13.7
Paying boarders ..	54	6	11.1	3	5.5
'Vernacular' day scholars ..	43	20	46.5	16	37.2
Boarded orphans ..	52	43	82.6	20	38.4

The degree of phrynoderma and 'sore mouth' in those children who paid fees was very slight, with the exception of three girls who had advanced phrynoderma, and two who also had 'sore mouth'. On enquiry into their circumstances it was discovered that they were sisters, and had lost their mother and were being 'cared for' by a guardian.

Example II.—An orphanage situated in a country district was inspected. When the inspection was finished, a visit was paid to a free vernacular school in the same district to enable a comparison to be made between the children

(Continued from previous page)

distinction between individuals of different age groups; had the adult population only been taken into consideration in appraising the value of this measure it might have been acclaimed as a success. (But in the absence of any comparable controls even this would have been questionable.) As it is, it must be reported as a failure, but only a failure as far as the special circumstances are concerned, and these appear to have been such that failure was a foregone conclusion.—
EDITOR, I. M. G.]

of the orphanage and those of the poorer classes living at home. Table II gives the results:—

TABLE II

	Number examined	SHOWING PHRYNODERMA		SHOWING 'SORE MOUTH'	
		Number	Per cent	Number	Per cent
Orphanage ..	130	83	63.8	33	26.0
Vernacular school ..	75	16	21.3	5	6.6

An enquiry was made concerning the morbidity and mortality at the orphanage, and it was obvious that both were very high but exact figures could not be obtained because it was customary to send sick children to their relatives or to hospitals and to avoid deaths taking place on the premises. Despite this it was found that among 313 children between the ages of 6 and 14 who had entered the orphanage there had been 18 deaths.

This is a death rate of 57 per 1,000 which is ten times as high as among children between these ages of the general population, where the death rate is 5.8.

Example III.—A drought affected the greater part of Ceylon during this year (1934), and this was particularly severe in the Northern provinces.

Mannar is a small town situated on a northern island, which is connected by a long causeway with the mainland. Here there had been no rain for seven months and it was reported that the inhabitants were unable to obtain sufficient food.

Before examining the children of this town, a village school twelve miles away on the mainland was visited. This village was situated between two large tanks and water was still available from one of them for the irrigation of gardens, and vegetables were procurable by the poorest classes. The diets of the children consisted of unpolished rice, fresh tank fish or dried fish, vegetables, and a small amount of fruit.

The vernacular children of Mannar were inspected on the following day. Their diets consisted of unpolished rice, dried or fresh sea fish, and the saccharine juice of the fruit of the palmyra palm, and a few children occasionally obtained a small amount of vegetables.

The country was parched and no leafy or ground vegetables were to be seen growing anywhere. In the compounds of the better classes there were seen shrubs and trees bearing 'vegetables' or fruits, such as drumsticks, pomegranates, limes and bananas, which were being irrigated with small amounts of water from wells.

The following table (table III) shows the comparison between the vernacular children of Mannar and those of the school in the village 12 miles distant.

TABLE III

	Number examined	SHOWING PHRYNODERMA		SHOWING 'SORE MOUTH'	
		Number	Per cent	Number	Per cent
Mannar ..	150	33	22	23	15.3
Village ..	70	4	5.7	6	8.6

Example IV.—In conversation with Dr. Crawford, the Government Veterinary Surgeon, I mentioned that milk or eggs quickly cured phrynoderma and 'sore mouth'. He remarked jokingly that the children of the coolies who milked the cows at the Government Dairy should be free from those conditions. An inspection was arranged and the next morning 46 children of the workers at the dairy were lined up. I picked out six children from different places in the line, four of them had marked phrynoderma two also showing 'sore mouth', the other two had slight phrynoderma. The rest of the children were not only free from these signs but also had unusually good teeth for this class of child in whom decay following hypoplasia is very common.

Dr. Crawford called for the fathers of the children I had picked out, one coolie claimed the four of them that had the most marked signs, and another coolie claimed the other two. The first coolie was in charge of the stud bull, he had nothing to do with the milking of the cows, and was of a different caste to the other coolies. The second coolie was a cleaner, who did not milk the cows.

Discussion

Other orphanages in Ceylon have been inspected and the results have been much the same as those given in examples I and II.

The children of these institutes usually are supplied with ample rice, and in the ordinarily accepted sense of the term they are not being starved. Undoubtedly those in charge of them would resent such a suggestion. The type of diet the poorer classes obtain in their own homes consists of rice, a small quantity of dried or fresh fish, vegetables, and the usual condiments for curry, also *dāl* or green gram may or may not be added to the curries.

Now there is a considerable difference when such diets are prepared by housewives, and when they are prepared in institutions. The

THROMBO-ANGIITIS OBLITERANS

By D. C. CHAKRAVARTI, F.R.C.S. (Edin.)

Surgeon, Campbell Hospital, Calcutta

THIS condition was recognized first by Von Winiwarter in 1879 and described by him as endarteritis obliterans. It has been fully described by Buerger recently, and it was he who gave it the name of thrombo-angiitis obliterans.

(Continued from previous page)

former have learnt to produce variety, especially with the vegetables. A number of different plants having edible leaves or fruits grow in the gardens and jungles, and these are obtained by the women of the indigent classes. There is a Sinhalese proverb which points out the necessity of a daily addition of green leaves to the diet. Also there are many varieties of dried fish. Therefore the housewives are able to mitigate the monotony of the daily curry.

The managers of orphanages obtain their supplies from the cheapest vendors. Only vegetables which are obtainable in bulk and are easily handled are supplied: and pumpkins, gourds, coarse cucumber, drumsticks and bread fruit in season are the main vegetables supplied. The dried fish is the cheapest obtainable. The diet may be varied by giving a *dāl* curry once or twice a week, and occasionally a meat curry. Fruit is seldom given.

It is this lack of variety which plays a great part in producing the signs of food deficiencies among the orphans.

A similar state of affairs has existed in the prisons (Nicholls, 1933). Many of the convicts come from the indigent classes, and in their normal lives they obtain only the barest of dietary necessities. The punishment factor in jail life has been accentuated in the past, and it has been judged unreasonable to supply convicts with a diet as good or better than that obtainable by them when at liberty.

The law has declared a penal diet, whereby a convict, during the first fortnight or month of incarceration, is supplied with a diet deficient in proteins and vitamins; and it is not astonishing that a large number of prisoners have shown phrynodema, 'sore mouth' and other signs of vitamin deficiencies.

The diets of the indigent classes being on the threshold of deficiency cannot be further reduced without affecting the health of those who consume them.

It is probable that in other tropical countries these two signs will be found of great value in checking up the adequacy of diet.

REFERENCES

- Nicholls, L. (1933). *Indian Med. Gaz.*, Vol. LXVIII, p. 681.
 Nicholls, L. (1934). *Ibid.*, Vol. LXIX, p. 241.

It is characterized by the following:—

(a) It is a disease of the larger blood vessels showing the histological characters of an inflammatory lesion. The larger arteries of the limbs are generally affected. Veins are also affected to a certain extent. Thrombosis occurs and is followed by organization of the clot. This produces embarrassment of the circulation.

(b) It usually occurs in males, generally between the 30th and 40th years.

(c) The lower limbs are more commonly affected than the upper.

(d) It is said to occur mostly amongst the Jews, but is found in other races.

(e) Its origin is not known. Michel in 1909 noted the importance of smoking as a factor in causing it, but it is not known if the bad effects are due to the vasoconstricting action of nicotine, or tobacco sensitization of endothelium of arteries and veins.

Symptomatology.—The patient's first complaint is intermittent claudication with the sensation of severe pain, rigidity or constriction about the calf of leg. The pain is produced and increased by exertion, e.g., walking. The ability to walk any distance gradually diminishes.

The cases are all bilateral but as a rule the symptoms are noticeable on one side more than on the other. Some cases also complain of vascular disturbance in the hands. These disturbances are of the nature of spasmodic Raynaud's type.

The feet are cold; their colour is dusky owing to cyanosis. Dependent position of the limb produces some degree of rubor in nearly all cases. It is marked by absence of pulse in the dorsalis pedis, posterior tibial, popliteal and even in the femoral arteries. Later on a peculiar rubor, oedema and trophic lesions appear, and, in more severe forms, gangrene develops calling for amputation. A common mode of onset of these grave troubles is by an onychia, usually of the great toe, the nail-bed being ultimately transformed into an intractable, callous and painful ulcer with no tendency to heal.

Superficial thrombo-phlebitis is occasionally found in association with it. Many of these cases suffer from intolerable rest pain which causes a rapid deterioration of health.

Pathological changes.—Telford and Stopford (1924) noticed the following changes in the vessels:—

'There is lymphocytic invasion of the coats of the arteries and veins. Cells are replaced by fibrous tissue and new vessels may be seen extending through the adventitia to the media. Along with these changes parts of the lumen become occupied by a clot which is gradually organized. In this obliterating connective tissue a number of small channels are found which have a lining of endothelium surrounding this; some possess a thin coat of smooth

muscles. After these changes have occurred in the lumen collections of lymphocytes not unlike tubercles often make their appearance and persist until they are replaced by fibrous tissue. There is some irregular thickening of the intima and only very slight proliferation of the internal elastic lamina. At a later stage the fibrous tissue in the lumen has a denser appearance, but this may partly be due to contraction of newly-formed fibrous tissue in the media and adventitia. This contraction may be an important factor in the production of gangrene, because it leads to compression and occlusion of many of the newly-formed smaller channels in the connective tissue in the lumen'.

Serum calcium and coagulability time do not show any change.

Duration.—Variable.

Syphilis.—This has nothing to do with the condition, as the Wassermann reaction is usually negative.

Treatment.—Various methods of treatment have been tried, e.g., periarterial sympathectomy, attacks on the suprarenals, injection of typhoid vaccine, acetylcholine, muscle extract and padutin, but they have failed to effect any permanent benefit.

Owing to the fact that this disease has an element of vasospasm, which is according to some the essential cause of the disease and according to others only a superadded factor, surgeons have suggested various forms of sympathectomy.

In order to enable the readers to follow the results of the operations described, an outline of the anatomical and physiological principles which underlie these operations performed on the sympathetic system is given below.

The peripheral portion of the sympathetic system consists of (a) preganglionic fibres, (b) ganglionated trunks, (c) visceral ganglia, (d) postganglionic fibres, and (e) rami communicantes.

Preganglionic fibres.—There are cells termed 'connector cells' in the lateral horn of the spinal cord which are present only in all the thoracic and the upper three lumbar segments.

The axons of these cells leave the cord in the anterior roots of the nerves arising from those segments. They leave the anterior roots in white rami communicantes and reach the sympathetic trunk and end by arborizing round the ganglion cells, etc. They convey impulses from the spinal cord to the sympathetic system and are termed by Langley 'preganglionic fibres'.

Ganglionated trunks.—These extend one on each side of the vertebral column from the base of the skull to coccyx. Each consists of preganglionic fibres and ganglion cells grouped together at intervals to form ganglia whose number does not tally with the segments of the cord. The cervical region has 3, dorsal 11 or 12, lumbar 4 and sacral 4. These are concerned

with sympathetic innervation of the extremities, head and neck and thoracic viscera. They have nothing to do with abdominal viscera.

Visceral ganglia.—The important ganglia in the abdomen are the coeliac, superior mesenteric and inferior mesenteric. Bundles of nerve fibres run to these ganglia from the trunks in the lower thoracic and lumbar regions and are termed thoracic and lumbar splanchnic nerves.

Postganglionic fibres.—Cells of both the trunk and the visceral ganglia are known as 'excitor cells' and their axons, the postganglionic fibres, pass ultimately to blood vessels, sweat glands, eye, thoracic and abdominal viscera. Bundles of these fibres are given off from all the ganglia of the trunks to join the spinal roots and every spinal nerve is thus provided with a sympathetic supply. These are known as grey rami communicantes.

Rami communicantes.—*White*—14 or 15 on each side, contain preganglionic fibres. All sympathetic impulses leave the spinal cord through these. *Grey*—more numerous, composed of postganglionic fibres, distributed through spinal nerves to blood vessels, sweat glands and arrectores pilorum muscles of head, neck, trunk and limbs. No impulses pass along these to thoracic and abdominal viscera.

Sympathetic supply to head.—The blood vessels of the head, neck and eye are supplied from connector cells in the 1st and 2nd thoracic segments whose preganglionic fibres leave the cord in the white rami communicantes and passing up the trunk end around the excitor cells in the superior cervical ganglion. Many of the postganglionic fibres pass thence along branches of the external and internal carotids, others accompany branches of the cervical plexus.

Supply to arm.—Connector cells for the arm lie in the mid-thoracic region from the 4th to 9th segment. Preganglionic fibres pass from these segments and ascend the trunk to end in the middle and inferior cervical, 1st and 2nd thoracic ganglia. Grey rami pass from these ganglia to the brachial plexus and are distributed with the branches of the plexus.

Supply to leg.—Connector cells are in the lowest three thoracic and upper three lumbar segments. Preganglionic fibres pass out in white rami and end in the 2nd, 3rd and 4th lumbar and in sacral ganglia. Grey rami from the 2nd lumbar ganglion downwards contain postganglionic fibres which are carried to the periphery through the lumbar and sacral plexuses. It is therefore clear that if the 2nd, 3rd and 4th lumbar ganglia and intervening portions of the trunk be removed, excitor cells to lumbar nerves and preganglionic fibres to sacral nerves will be removed and sympathetic denervation of the leg will be thus achieved.

The following case will show the effect of lumbar sympathectomy :—

D. P. D., Hindu male, aged 35 years, occupation, clerk. Admitted on the 28th October, 1933.

Chief complaints.—Inability to walk even for a short distance without severe pain in the calf of the right leg and foot; sensation of cold in the affected limb; bluish discoloration of the right foot and leg extending up to the knee joint and pain relieved by the application of warmth and keeping the limb elevated.

It was stated by the patient that he had been keeping very good health before this. No history of venereal disease.

Wassermann reaction, negative. He was in the habit of smoking 15 to 20 'biris' (country-made cigarettes) daily. No pulsation of the dorsalis pedis, posterior tibial or popliteal could be felt. Femoral pulsation could be easily felt and was similar on the two sides. The right saphenous vein was very prominent and felt like a cord, it was very tender to touch up to the knee joint. Muscles of the affected limb were atrophied, due to disuse; otherwise motor and sensory functions were normal.

Blood pressure.—Systolic, 130 mm. Hg.; diastolic, 90 mm. Hg.

Treatment adopted.—As the patient's general condition was very poor and as he was not considered a fit subject for operative treatment a conservative measure in the form of padutin injection was tried with the idea of causing dilatation of minute vessels. Twelve injections were given, 1 c.cm. daily.

Effects.—The pain was much less, the leg became warmer than before, discoloration was much less, the patient could walk a little distance without the cramp-like pain, and the blood pressure was reduced—systolic, 110 mm. Hg.; diastolic, 80 mm. Hg.

He was discharged relieved on the 3rd December, 1933, but was readmitted on the 24th February, 1934, with the complaint that all the symptoms had reappeared a fortnight after his discharge from the hospital. Besides his usual complaints he came to the hospital this time with gangrene of the tip of the right great toe. General health was almost the same as before, but he was absolutely crippled, complaining of constant severe pain even at rest. Pain was so severe that the patient had to be given morphia twice daily.

Operation.—Lumbar sympathectomy was performed under general anaesthesia on the 6th March, 1934.

The abdomen was opened by a right paramedian incision about six inches long. The incision was partly above and partly below the umbilicus. The coils of the small intestine were packed off to the left and the posterior parietal peritoneum was incised just lateral to the caecum and ascending colon. The colon was pushed

aside exposing the right psoas major muscle, ureter and inferior vena cava. After identifying these, the inferior vena cava was retracted gently to the left and the psoas major to the right. The gangliated cord of the sympathetic was found lying near the medial border of the muscle on the bodies of the lumbar vertebrae. The duodenum was pushed upward and the second lumbar ganglion was identified and the trunk cut just above this ganglion. The trunk was then traced downward and found passing behind the right common iliac artery. It was divided below at this level and this portion of the trunk with the second, third and fourth ganglia was removed. The colon was placed back in position after arresting very troublesome haemorrhage from the lumbar veins and the posterior parietal peritoneum was stitched up. The abdominal wall was closed without any drainage.

Effect of the operation.—Its effect was like magic, because the patient was relieved of his excruciating pain immediately. The affected part became warmer gradually. Unfortunately the patient passed through a very stormy convalescence as he developed post-operative pneumonia and his condition was very critical. However, he got over this and was discharged very much relieved on the 16th April, 1934.

He was again admitted for the third time on the 13th June, 1934, for gangrene of the right great toe. Lumbar sympathectomy had no effect on this toe. It showed an ulcer covered with slough a little proximal to the interphalangeal joint. The last phalanx was protruding through the slough. There was bluish discoloration of the skin round the base of the toe. His general health had improved considerably. Bluish discoloration of the skin of that leg almost disappeared. He said that he had not experienced the constant pain after the operation, but complained of pain only in the affected toe.

Treatment advocated by Saul S. Samuels (1934) was strictly followed this time :—

Rest in bed, the extremity being constantly kept in a horizontal position.

No smoking.

Intravenous saline injection; in this case fourteen injections of 300 c.cm. of a two per cent solution were required.

[Mayesima in 1911 observed increase in the viscosity of the blood in these cases, so he advised intravenous saline injection of 250 to 300 c.cm. of a two or three per cent solution daily.]

Local treatment to aid in the development of the line of demarcation, to maintain the dead and dying tissues as aseptic as possible, and to control pain, a foot-bath of borie lotion and an anaesthetic ointment of camphor and phenol one per cent each were applied to all exposed areas.

The last phalanx dropped off, the ulcer healed up quickly and the local pain disappeared.

A case of symmetrical gangrene treated by cervical ganglionectomy

I. B., Mahomedan male, aged 40 years, occupation, cultivator. Admitted into the Campbell Hospital on the 6th January, 1934.

Chief complaints.—Pain in the fingers and both forearms; pain in the toes and feet, more marked in the left, but it started in the right side first; callous ulcer on the right index finger, intermediate phalanx being bare and protruding through the middle of the ulcer; the last two phalanges of the left index and ring fingers said to have dropped off, stumps showing irregular scar tissue; an ulcer on the dorsal aspect of the right great toe showing no tendency to heal; and the right little toe was said to have dropped off about 10 months before admission.

Duration.—A year and a half.

On examination no pulsation of either radial and ulnar arteries could be elicited. Absence of pulsation of right dorsalis pedis and posterior tibial. The right hand and forearm were colder than the left. The right index finger was gangrenous, there was no line of demarcation and the discharge was purulent and very offensive. No thrombo-phlebitis was present. Wassermann reaction, negative. Patient's general condition was good. He was in the habit of smoking 'biris'.

Blood pressure.—Systolic, 100 mm. Hg.; diastolic, 70 mm. Hg.

Patient being a male, and pulsation of arteries being absent, the case was thought to be a case of thrombo-angiitis obliterans affecting all the four limbs. This is very rare indeed.

Treatment.—Padutin injections were first tried without any results. The patient would not submit to laparotomy, so cervical ganglionectomy operation was performed on the right side on the 5th March, 1934.

Operation.—A collar incision was made just above the right clavicle about four inches long. Skin, superficial fascia, platysma and fascia colli were cut. The external jugular vein was ligated in two places and was cut in between. The inferior belly of the omohyoid was found and divided, and the scalenus anterior and the phrenic nerve lying in front of it were exposed. The nerve was retracted medially and the muscle was cut transversely a little above its insertion; thus the second part of the subclavian artery was fully exposed. It was now necessary to ligature and cut the transversus colli artery. Sibson's fascia was separated from the inner border of the first rib

(Continued at foot of next column)

OBSERVATIONS ON SPINAL NOVOCAINE ANÆSTHESIA

By R. VISWANATHAN, B.A., M.D., M.R.C.P. (Lond.)
General Hospital, Madras

THE object of this short paper is not to discuss the technique of spinal anæsthesia, but to record untoward symptoms observed during the period the patient is under the influence of

(Continued from previous column)

by the pressure of the index finger and the subclavian vessels and the dome of the pleura were pushed downward. The inferior cervical ganglion was identified lying on the neck of the first rib. The first and the second thoracic ganglia were identified and the sympathetic trunk was cut transversely below the second ganglion. The cut end was reflected upward and the connections of the ganglia with the brachial plexus were cut and the trunk was divided above the stellate ganglion. The soft tissues were placed back in position, the fascia colli was stitched up and the wound was closed without any drainage as there was practically no bleeding.

Results of the operation.—Ptosis was marked, the conjunctival vessels were engorged, the tension of the eyeball was less, the palpebral fissure was considerably reduced, and the right pupil was contracted. These physiological effects lasted for about a month. He was seen three months after the operation and the above-mentioned eye changes were almost absent.

Forearm and hand of that side were distinctly warmer. No change in the pulsation of the radial and ulnar arteries was noticed.

There was a marked change in the ulcer of the right index finger. There was a distinct line of demarcation and the necrosed phalanx dropped off. Later on a disarticulation was performed through the metacarpophalangeal joint and the wound healed by first intention.

No weakness of the muscular power was noticed. The patient never complained of pain in that hand and forearm.

As the patient refused laparotomy for lumbar sympathectomy which was considered necessary for the toes, he was discharged on the 4th April, 1934.

the anæsthetic and also the variations in blood pressure, which have enabled me to draw some conclusions regarding indications and contra-indications for spinal anæsthesia, so far as blood pressure alone is concerned.

Amounts varying from 13 to 16 c.cm. of a 1 per cent solution of novocaine for high and from 1½ to 2 c.cm. of a 7½ per cent solution for low spinal anæsthesia were used.

A small percentage of patients exhibited no untoward symptoms. Some complained of a feeling of oppression in the chest soon after the injection. About 90 per cent of the patients who had no form of pre-operative treatment vomited, some only in the beginning, others throughout the operation. About 50 per cent of them sweated profusely. Other symptoms such as yawning, restlessness, difficulty in breathing, a tendency to stretch the arms, ineffectual attempts to move the anæsthetized portion of the body, hiccough, mental confusion, and intense thirst were observed at times.

With the help of the house-surgeons in charge of the surgical wards, I adopted the following pre-operative treatment in twelve cases, choosing them indiscriminately.

Three doses of a mixture containing 10 minims of tincture of belladonna and a drachm of sodium bicarbonate to an ounce of water were

given beginning from the evening prior to the day of operation. Half an hour before the thecal injection, a ¼ grain of morphia and 1/75 grain of atropine were given hypodermically. Ten out of twelve patients were absolutely quiet throughout the operation. The other two had only slight nausea. I consider that the above form of pre-operative treatment should be effective in all cases of spinal anæsthesia, as most of the untoward symptoms observed are due to sympathetic paralysis and consequent relatively excessive vagotonia. In fact it is the vagotonies who suffer more than the sympathetico-tonies. The latter are really the few people who stand spinal anæsthesia very well without the aid of any form of pre-operative treatment.

Blood pressure readings were taken before and immediately after the spinal injection, and also every five minutes throughout the operation. A half c.cm. of adrenalin was given as a routine in all cases. Although it might have modified the actual variations in blood pressure, it does not materially modify our deductions, as adrenalin was used in all cases.

I am inclined to draw the following tentative conclusions, though they require to be substantiated by further observations.

THE INFLUENCE OF FRESH BILE ON GUINEA-WORM LARVÆ ENCYSTED IN CYCLOPS

(A PRELIMINARY REPORT)

By V. N. MOORTHY, BSC, M.B., B.S., D.P.H., D.T.M.

Guinea-worm Research Officer

Office of the Director of Health, Bangalore

WHILE conducting a series of infection experiments of *Barbus puckelli* fish with guinea-worm embryos it was noticed that, in specimens of the fish that had died of very heavy infection, the gastro-intestinal tract was invariably flooded with a large quantity of bile. This observation suggested the study of the effect of fresh fish bile on guinea-worm embryos and also on cyclops infected as well as uninfected. It was found that fresh bile of the following species of fish, *Barbus puckelli*, *Barbus punctatus* and *Barbus gelius*, exerts a definite lethal action on cyclops and also on guinea-worm embryos. When undiluted fresh bile was used, it was found that it took about one to two minutes to kill the cyclops and two to three hours to kill the embryos. When its effect on cyclops infected with guinea-worm embryos a fortnight before was observed, it was interesting to note that it had identically the same effect as 0.2 per cent HCl first described by Leiper (1906). It killed the cyclops in the course of one to two minutes and activated the encysted larva. The larva thus activated disorganizes the entire internal structure of the cyclops by its powerful coiling, uncoiling and twisting movements and, in some, it even succeeds in finally escaping out of the body cavity of the

cyclops after about thirty to thirty-five minutes by making an opening through the most vulnerable portion of the cyclops. The position of release seen in the photomicrograph (figure 1)—the junction of the anal segment with

Fig. 1.—Photomicrograph of cyclops infected with guinea-worm embryos 15 days previous to the experiment and treated with the bile of *B. puckelli*. The larva was killed by 30 per cent formalin solution when it was just escaping from the cyclops and then was mounted in two per cent glycerine formalin solution. The larva is seen just escaping through an opening it had made in the cyclops at the junction of the caudal ramus with the anal segment.

(Continued from previous page)

(1) The fall in blood pressure is great in a patient with high diastolic and low pulse pressure. Hence spinal anæsthesia is contraindicated in such cases.

(2) Provided the cardio-vascular system is otherwise normal, a systolic pressure even as low as 80 with a diastolic pressure of 45 or over is no contraindication for spinal novocaine anæsthesia. On the other hand I consider such patients better suited for spinal novocaine anæsthesia, as the system is more adapted to low blood pressures.

(3) Diastolic pressure below 40 is a definite contraindication.

(4) The fall in blood pressure is slower and steadier when the initial blood pressure is low.

I have deliberately made these conclusions dogmatic, with the idea of stimulating discussion from anæsthetists, based on their own personal experiences.

My thanks are due to Colonel K. G. Pandalay, I.M.S., and Dr. Mangesa Rao, for the facilities they have given me for making these observations.

the furcal rami of the cyclops—was the most common site through which the guinea-worm embryo escaped. The result was the same when the infected cyclops was treated with fresh goat's bile and sheep's bile, but the time taken to kill the cyclops was nearly thirty to thirty-five minutes and it took on an average sixty-five minutes for the encysted larva to escape. Observations so far made with human bile got by post mortem six hours after death, from a case of suicidal hanging, indicate that it also has an identical effect on infected cyclops; the larva is not, however, activated to the same extent as in the case of fish bile; it takes on an average twenty minutes for the cyclops to be killed and seventy-nine minutes for the encysted larva to escape from the cyclops.

In all the observations made by N. Hamilton Fairley and W. Glen Liston (1924) they have found that, though saliva and pancreatic juice (artificial) had definite lethal action on cyclops,

these secretions did not stimulate the encysted larvæ and in none of the specimens of infected cyclops treated with these secretions did the larvæ escape out of the body cavity of cyclops

Fig. 2—Photomicrograph of infected cyclops treated with the bile of *B. gelius*. A. Fish gall-bladder opened to let out bile. B. Infected cyclops lying on the fish gall-bladder. C. The guinea-worm embryo that escaped from the cyclops when treated with fish bile. D. Anal segment of cyclops through which the embryo escaped

unless mechanical trauma was superadded. The action of fresh bile on infected cyclops seems thus to differ from the action of these digestive secretions in that it not only kills the cyclops but also activates the encysted guinea-worm embryo which in some cases even escapes out of the body cavity of the cyclops. It is also of interest to note that fresh bile, though alkaline in reaction, has the same stimulating effect on the encysted guinea-worm larvæ lying in the body cavity of the cyclops as 0.2 per cent HCl, i.e., the percentage of HCl found in the normal gastric juice of human beings.

Since it was clear from the above experiments that fresh bile had practically the same effect on infected cyclops as human gastric juice, an attempt was later on made to determine whether the liberated guinea-worm embryo undergoes any further developmental changes in the gastro-intestinal tract of *Barbus puckerli* in the same manner as it does in human beings. Such infection of fish with other parasitic

nematodes is not unknown; for instance in *Camallanus lacustris* infection first worked out by Leuckart (Henry B. Ward and George C. Whipple, 1918) the mechanism of infection is recognized to be due to the fish feeding on cyclops infected with *Camallanus lacustris* larva. The larva gains entrance to the cyclops and bores its way into the body cavity where the first moult occurs. Later it moults once or twice again and in addition undergoes certain developmental changes such as losing its tail in part, developing an oral armature and bipartite œsophagus, etc., resembling thus to a large extent the developmental changes of the guinea-worm embryos that take place in the body cavity of cyclops. The period required for these developmental changes to take place varies from about three days in summer to three weeks in winter. Further developmental changes take place in the alimentary canal of a suitable fish host where, after ingestion, the worm, if set free from the larval host, grows rapidly and in about ten to fourteen days the young worm becomes fully mature and pairs. Observations so far made on fish fed with cyclops infected with guinea-worm embryos, a fortnight before the experiment, and the examination of their intestinal contents at definite periodical intervals have shown the presence of nematode larvæ which appear to be the developed stages of guinea-worm embryos. This work is still in progress and full experimental details will be published in a subsequent communication.

I am greatly indebted to Dr. J. V. Karve, Director of Health in Mysore, for the very valuable help and guidance which he has given me in doing this work. My thanks are also due to Mr. L. N. Rao of the Central College, Bangalore, for having kindly helped me in taking the photomicrographs.

Summary of observations

1. Fish bile has a definite lethal action on cyclops and guinea-worm embryos and on infected cyclops it has identically the same action as 0.2 per cent HCl, i.e., it kills the cyclops and activates the encysted larva and, in some, the larva finally escapes out of the body cavity of the cyclops by making an opening generally in the last segment of the abdomen or in the caudal ramus.

2. Human bile, goat's bile and sheep's bile have also the same effect on cyclops and infected cyclops as fish bile.

3. When *Barbus puckerli*, *Barbus punctatus* or *Barbus gelius* is fed with cyclops, infected with guinea-worm embryos a fortnight before, the liberated embryos appear to undergo further development in its gastro-intestinal tract.

A SIMPLE FLY TRAP

By J. F. JAMES

LIEUTENANT-COLONEL, I.M.S.

Commanding Officer, Combined Indian Military Hospital, Razmak

In dealing with flies, apart from preventive measures in limiting breeding grounds, the sugar, or *gur*, arsenic poison is a most effective one especially in dry weather.

The solution consists of :—

Sugar, molasses or <i>gur</i>	1 lb.
Arsenite of soda	1 lb.
Water	10 gallons.

It is extremely poisonous to human beings and animals and care should be taken that the latter do not obtain access to it.

The wooden trap with rollers usually employed to exhibit the poison has been found to be somewhat unsatisfactory, as, apart from its cost, it is liable to leak and to breakage.

After considerable experiment the following pattern has been devised :—

An empty *ghi* tin is placed upright and cut across the top medially. A similar cut is made parallel across the front of the tin about three inches from the bottom and the cut extended up each side to meet the top cut, the part removed being shaped like a banker's shovel. A modified pattern is made by cutting perpendicularly through the top to within three inches of the base and then horizontally through half the tin. A stout wire is passed across the top of the tin about two inches from the back and looped above to enable the tin to be hung on a wall or other support. (This is not shown in the sketch below.)

The portion of wire across the inside of the tin serves as a support for *gunny* or other material. The *gunny* should extend to the

bottom of, and also cover the floor of, the tin. The upper part of the *gunny* can be wetted with the poison solution by laying the tin flat. The lower part is of necessity always wet. The reservoir for the poison solution is the lower three inches of the tin and about one inch depth of solution is ample.

These *ghi*-tin fly traps can be turned out very quickly at a cost which is negligible. About 400 of these or a similar pattern are at present in use in this station. They are collected, cleaned and the solution changed twice weekly under the direct supervision of a sanitary inspector.

The *ghi* tins referred to measure about 14 inches by nine inches by nine inches and would be available on service in the field. Smaller or larger tins can however be similarly cut to serve the same purpose, e.g., gallon tins which are used for lubricating oil.

A Mirror of Hospital Practice

A CASE OF RECURRENT VITREOUS HÆMORRHAGES

By G. S. GUHA, M.B.

Laitumkrah, Shillong

J. R. M., a young male working as a laboratory assistant at the Pasteur Institute, Shillong, was sent to me by the Assistant Director of the Institute for examination of his right eye. The patient complained of sudden dimness of vision in his right eye without any apparent cause such as trauma or any sort of muscular strain. On external examination, nothing abnormal was found except that the vision in that eye was reduced to finger counts only at a distance of about three metres. On ophthalmological examination, a big speck of hæmorrhage was found as shown in figure 1. The fundus looked hazy, probably due to an

Fig. 1.

accumulation of blood in the vitreous. The patient was advised absolute rest in bed. His blood was then

examined for the Wassermann reaction which was absolutely negative; the urine was also found to be normal. No other septic focus, *c.g.*, in the teeth or tonsils, could be found. After a few days' rest in bed the bleeding spot seemed to be a little smaller. He was then put on an iodide mixture. For the first three or four days, he did not note any change in the vision of his affected eye but later on he complained of a further loss of vision. On ophthalmological examination, it was practically impossible to see the fundus owing to a darkish haze in front, caused no doubt by an accumulation of blood in the vitreous. Thinking that a further bleeding had taken place, I gave him a few calcium injections. In addition he was given subconjunctival saline (normal) on every alternate day in doses of 0.2 c.cm., 0.4 c.cm., 0.5 c.cm., 0.5 c.cm., 0.5 c.cm., and 0.5 c.cm. After this course of subconjunctival saline was over, his right eye was again examined by the ophthalmoscope and it was found that the haze in the vitreous was much reduced but another small speck of hæmorrhage (as shown in figure 2) and some opacity

Fig. 2.

in the lower portion and in front of the fundus was seen. The patient was again given subconjunctival saline (double strength of normal saline), put on an iodide mixture of thirty grains of potassium iodide per dose, twice daily after food, and calcium injections in the form of colossal calcium with vitamin D (Glaxo) twice weekly. The patient gradually noted an improvement in his sight. His vision in the right eye is at present 6/9. But on movement of his eyes up and to the sides, he complains of seeing some screen-like shifting opacity in front of the right eye. On ophthalmological examination, I found the fundus to be absolutely clear except that in the lower portion a small area of a glistening fibrous band of tissue, probably retinitis proliferans, extended into the vitreous.

Recurrent hæmorrhages in the vitreous, known as Eales' disease, usually affects both eyes and is commonly due to deficiency of some blood constituent or to the changes in the endothelium of the retinal vessels due to some toxic products. The condition has also been thought to be of a tuberculous or tuberculo-allergic nature.

A CASE OF STRANGULATED HERNIA

By A. F. W. DA COSTA, F.R.C.S.E., D.T.M., L.M.S., V.D.

MAJOR, I.M.D.

Kamptee Road, Nagpur

Mr. H. K., aged 30 years, well built, an athlete, was admitted into the hospital for vomiting and unbearable pain in the right pubic and scrotal regions which began

at 3 a.m. the same morning. On admission the pulse was 86 per minute, temperature 98°F., respiration—21 per minute, tongue—dry and thickly coated.

The complaint about a swelling appearing and disappearing in the right pubo-inguinal and scrotal area had been of twelve years' duration. The swelling, which used to descend into the scrotum from the abdomen, appeared almost invariably after exertion in the gymnasium and occasionally used to be painful, but after rest the pain and swelling used to subside completely.

At about 2-45 a.m. on the day of his admission to hospital he had a severe fit of coughing, which brought on the swelling in the scrotum and along with it pain which gradually increased and became intense.

I examined him carefully and found the hernia to be of a direct type and irreducible and the man was in agony. The hernial swelling was of the size of a big coconut, resonant, but without a gurgle; in fact with all the signs and symptoms of a strangulation. At 1 p.m. the same day after an injection of stovaine into the spinal theca and a subcutaneous injection of 1 c.cm. adrenalin, a three-inch incision immediately above the base of Hesselbach's triangle was made and the hernial sac, which looked blackish, identified. On opening the sac a purplish black fluid welled out and a fifteen-inch-long loop of gut near the ilco-caecal valve was found to be almost gangrenous. It was rigid, purplish black, along with its mesentery which looked and felt the same. There was no visible or palpable sign of pulsation in the arteries. An enterectomy looked obvious but I tried and succeeded in resuscitating the gut, after removing the constriction, with very hot saline for fully eighty minutes. To my surprise and also that of my assistants the gut began very gradually to revive until the whole coil of intestine with its mesentery became active, excepting a patch one and a quarter inches long and three-quarter inch wide on the side of the gut and a triangular patch of mesentery about one and a half inches long and an inch and a quarter wide at its base which remained purple and hard. Further efforts to revive these patches failed, so I decided to return the coil to the abdomen with the big gangrenous patch on the bowel and mesentery, although it was against all the canons and rules of surgery.

In the evening as the general condition was bad (the abdomen was tympanitic, no flatus had been passed even with a flatus tube) I decided to administer pitressin.

I commenced giving it every four hours and applied turpentine stupes to the abdomen four-hourly. Next morning he passed urine by himself to my great satisfaction and within forty-eight hours the tympanites started diminishing and some flatus was passed through a flatus tube.

He was kept on continuous glucose 5 per cent per rectum (not glucose saline), one pint every hour for six hours and then one pint four-hourly until ten pints were administered in the twenty-four hours; glucose water alone by mouth was given for four days after the operation. This was followed by barley water and glucose-D and fruit juice (of grapes, oranges, sweet limes and pomegranates) until the end of the first week. By the end of two weeks a normal diet was allowed.

He was discharged cured on the twenty-second day after operation.

He could have been discharged on the fourteenth day without danger, but I was anxious to observe the behaviour of his intestinal mechanism. As a matter of fact, it is always wise to keep an operated hernia case in bed for three weeks. I saw him two months later when he told me he was so fit that he had already begun his gymnastics as he could not resist the temptation, despite my telling

him to go easy for three months at the very least.

Commentary.—I am of opinion that this case teaches one not to be so cautious in replacing into the abdomen intestine which has been strangulated and which has revived almost completely. In due course of time with wise and appropriate after-treatment the patches of bowel, which does not appear normal before being returned to the coeliac cavity, will ultimately recover without any untoward symptoms. [On the other hand the 'canons of surgery' are based on the long experience of many surgeons and cannot be upset by a single experience of one surgeon.—EDITOR, I. M. G.]

A CASE OF SURGICAL EMPHYSEMA*

By S. N. SEN, L.M.P.

Assistant Medical Officer, Tata's General Hospital
Jamshedpur

In February last on returning to my native village I was called in to see a patient—a breast-fed male child about four months old—with the following symptoms, namely, restlessness, œdema from the chest upwards and dyspnoea.

Previous history.—No definite history could be obtained from the parents. They stated that about ten days ago the child had cried for a whole day and night, after which the above symptoms had gradually developed. A local physician suspecting diphtheria had given an injection of the anti-serum, which however had failed to produce any improvement. On thorough examination of the child, I came to the conclusion that it could not be a case of diphtheria. There was no patch, congestion nor œdema inside the throat; salivation was absent; there was no difficulty in swallowing or sucking; the expression was anxious, respiration hurried and there was movement of the alae nasi. On palpation the liver was felt rather more than an inch below the right costal arch; the spleen was not enlarged. On the right side from the head down to the chest emphysema could be noted under the skin; this was particularly noticeable over a spot between the sixth and seventh ribs which was tender to pressure. The abdomen was slightly tympanitic and a slight degree of emphysema was present over the upper right quadrant. The knee jerks were normal, the pulse was 90 per minute, tension fair, respiration—60 per minute and shallow; the temperature was 97.8°F. and never exceeded 98°F.

From the emphysema and pain it struck me that there must be some injury to the lungs. I enquired thoroughly to find out if the child had had a fall or any injury to the chest; this however was denied until finally an old woman attendant admitted that the child had accidentally fallen over a verandah about ten days previously. This fact had been suppressed as her negligence was responsible for the accident.

No medicine was prescribed for internal use except a few drops of brandy every four hours. The œdematous parts were bandaged and after two days the emphysema commenced to disappear. The child recovered completely a fortnight later.

A history of a fall from a height, the presence of emphysema, the negative signs of diphtheria and the failure to respond to the anti-serum proved clearly that the symptoms could not be due to that disease. It was purely a case of injury to the lungs following a fracture of the ribs although no signs of fracture could be

detected. The œdema was probably secondary to the emphysema.

A CASE OF ABSCESS OF THE SPLEEN IN MALARIA

By N. S. PILLAI, L.M.P.

Sub-Assistant Surgeon, Civil Hospital, Kyauktan
Burma

MA K. S., a Burmese female, thirty-nine years of age, was admitted to the Civil Hospital, Kyauktan, on the 12th March, 1934, suffering from an attack of fever with chills of twenty days' duration. She hailed from one of the villages of this township which was heavily infected with malaria. Her anæmic and emaciated condition showed that she must have been suffering for a longer period than she was aware of. Benign tertian parasites were found in the blood. The spleen which was enlarged (two finger-breadths) was bulging below the costal margin; the anterior margin was rounded and the notch was obliterated. The organ was freely movable, heavy, tense and gave a feeling of fluid contents. Although deep-seated pain was complained of there was no tenderness over the spleen. Under a course of quinine treatment her temperature became normal after six days. The condition of the spleen remained the same although the pain was said to have been slightly relieved. She was discharged from the hospital on the 31st March with instructions to come back if the splenic swelling increased or grew painful. Accordingly she came back on the 14th April with fever complaining of increased pain in, and swelling of the spleen. On examination it was found to have grown larger in size extending three inches inwards and downwards. It was immovable and the skin over the part was stretched, hyperæmic and œdematous, showing that adhesions had formed. It was thereupon decided to open it. The swelling was first explored with a hypodermic needle when pus was found. Under novocain adrenalin infiltration, a vertical incision one and a half inches long was made over the area just below the costal margin in the anterior axillary line dividing the skin and muscles and the swelling was opened with the blades of a sinus forceps. Nearly a pint and a half of thick dusky-white pus of a peculiar odour (not that of *Bacillus coli* infection) was evacuated without exerting much pressure. A rubber tube four inches long was introduced into the abscess cavity and stitched to the skin. The skin incision was closed above and below. The patient was immediately relieved of the pain and her temperature which was 101°F. on admission came down to normal on the fourth day. The abscess drained well and the cavity rapidly closed up. The patient began to move about on the tenth day. She had, however, another attack of fever with chills on the 6th May and again benign tertian parasites were demonstrable in her blood. Another course of quinine treatment was given. The fever lasted only one day. Thereafter, the patient improved steadily in health and her weight increased. She was discharged from the hospital completely cured on the 20th May. I saw her again on the 12th June. She looked quite well and cheerful. The spleen was felt just below the costal margin and was fairly movable. The anterior margin was thickened and the notch was not felt.

The inflammatory enlargement of the spleen being a marked feature in malaria, may it not safely be assumed that malaria was the cause in this case of the enlargement and suppuration which is one of the usual terminations of all inflammatory phenomena? I regret very much that I did not take a smear of the pus as soon as the abscess was opened and thus valuable

* Rearranged by Editor.

information that could have been gained was lost. Subsequent examinations were not useful as the wound became contaminated.

[Note.—It can hardly be assumed that malaria was the cause of the suppuration. It is much more likely that some infection, possibly pyogenic, was lying latent in the spleen to become active when conditions were favourable for it, i.e., during an attack of malaria.—*EDITOR, I.M.G.*]

TREATMENT OF ACUTE BACILLARY DYSENTERY WITH ANTI-DYSENTERIC SERUM AND BACTERIOPHAGE

By DHIRAJ MOHAN ROY, M.B.

District Medical Officer, Nepalgunj

ON the morning of the 16th May, 1934, I was called in to see a Hindu girl, aged 11 years, who was suffering from a sudden attack of dysentery of about twenty-four hours' duration. Her temperature was 100°F. I gave her a saline mixture containing sodium sulphate and magnesium sulphate.

When I went to see her in the evening, she had had thirty motions during the day, and her temperature was 101°F. She was given half a grain of emetine subcutaneously. Next morning her condition was no better, and another half grain of emetine was administered. In the evening I found her condition the same as before and the motions were just as frequent.

As there was no improvement whatsoever from the emetine given I thought it to be a case of bacillary type and, although there was no laboratory help available, I ordered a supply of anti-dysenteric serum and bacteriophage. As a temporary expedient I gave her an injection of kurchinatum which is claimed to act both in amoebic and bacillary dysenteries.

On the morning of the third day the specific remedies for bacillary dysentery arrived and I gave her 10 c.cm. of the polyvalent anti-dysenteric serum intramuscularly and one ampoule of the bacteriophage by mouth. In the evening 10 c.cm. of the serum was repeated and one ampoule of the bacteriophage. The saline mixture was continued as usual. On the morning of the fourth day I found the patient a little relieved but there was no marked improvement. Ten c.cm. of the serum was injected morning and evening and one ampoule of bacteriophage given thrice daily. On the morning of the fifth day there was a marked improvement and the number of motions in twenty-four hours were reduced to half. Ten c.cm. of the serum and the bacteriophage was repeated morning and evening on that day. On the morning of the sixth day there was a further improvement in the patient's condition. She had had ten to twelve motions in twenty-four hours, although mucus and blood still persisted and no natural stool was passed in any of the motions. As the patient was very young and unable to bear the pain of injections any more, I gave her 25 c.cm. of the serum along with the bacteriophage as usual, thrice daily by mouth. On the morning of the seventh day she began to pass stools with some of the motions, although there were still traces of mucus and blood.

After a total injection of 85 c.cm. of polyvalent anti-dysenteric serum and twelve ampoules of dysentery bacteriophage by mouth her condition was well under control. The specific treatment was then discontinued and bismuth mixture given. After taking bismuth for two or three days she began to pass normal stools and made an uneventful recovery.

One unusual feature of the case was that she had no tenesmus throughout her illness, which is so constant a symptom of all dysenteries.

The first part of the treatment given, namely, emetine and kurchinatum, will be criticized by some as it was mere guess work without being definite about the type of infection. In the mofussil where one cannot get laboratory help one has to take recourse to such intermediary methods such as emetine hypodermically and saline by mouth, at least as a therapeutic test similar to quinine in kala-azar.

I am indebted to Dr. S. K. Sen, M.D., chief medical officer, Nepal, for his kind permission to publish this case note.

DIPHTHERITIC CONJUNCTIVITIS

(A REPORT OF TWO CASES)

By V. C. RAMBO, M.D., F.A.C.S.

*Mungeli Area Christian Hospital and Dispensaries
Mungeli, Central Provinces*

EVEN in areas in which epidemics occur diphtheritic conjunctivitis is not a common occurrence. For this reason two cases diagnosed as diphtheria of the conjunctiva, which came to the Mungeli Area Christian Hospital for treatment, are presented. The first case is presented by the courtesy of Dr. T. P. Tiwari, assistant medical officer, Mungeli, who referred the case to me for treatment and gave me the notes on the preadmission history of the child. Before reporting these cases a brief mention of some of the characteristics of this condition will be made along with some quotations from Fuchs' textbook.

Conjunctivitis diphtheritica is one manifestation of infection with Klebs-Loeffler bacilli.

Case 2—Diphtheritic conjunctivitis.

Fuchs divides this form of conjunctivitis into two forms, (a) superficial, in which the grey white membrane clings to the conjunctiva but which can be removed, (b) deep (conjunctival diphtheria in the strict sense), in which the lids are swollen, red, hot and tender. The exudate

within the tissues of the conjunctiva are coagulated, the vessels are compressed, the mucous membrane becomes stiff and devoid of blood and falls a prey to necrosis.

Von Graefe distinguishes two types, 'In the milder cases one finds the diphtheritic spots in the conjunctiva in the shape of larger and smaller islands' (especially in the lid conjunctiva) between which less diseased portions of the conjunctiva lie. In the severe cases on the other hand the diphtheritic areas rapidly run together so that the entire conjunctiva is stiff and empty of blood'. Other cases are abortive and still others are very mild ones in which there is simple catarrhal inflammation only.

In the differential diagnosis various false-membrane-producing conditions must be taken into consideration. These may be either chemical or parasitic. Gentle brushing with ammonium or silver nitrate will cause a conjunctiva to present a light membrane while prolonged contact will produce a severe deep necrosis and deep membrane. Gonococci, streptococci, and certain bacilli may alone cause a membranous conjunctivitis or may make a diphtheria bacilli infection very much worse. In certain severe cases the accompanying streptococcal infection may present any number of streptococci in a smear, hiding the diphtheria bacilli, which may not be found, but still cause their characteristic symptoms and signs.

It can often be established that the children who suffer from a conjunctival diphtheria have been associated with others who shortly afterwards come down with pharyngeal diphtheria. The disposition to diphtheria decreases with age. Adults are only exceptionally attacked by this disease and then usually it is of a much milder type.

Case 1.—A child, two years of age, while being treated for a hopelessly advanced cirrhosis of the liver suddenly developed one morning swelling of the right eyelids. The palpebral conjunctiva was injected and there was a considerable amount of laceration. The case was taken for one of catarrhal conjunctivitis and protargol drops were ordered after irrigation with warm boracic solution. Next morning the eyelids were found sticking to each other. After separating them, the conjunctiva was examined and found to be covered with a thin greyish-white membrane. Diphtheritic conjunctivitis was thought of and a smear was taken for microscopic examination. This examination showed various cocci and bacilli but failed to reveal anything like a diphtheria bacillus, and therefore no serum was administered. Irrigation with mercury perchloride 1/6000 was performed and a light application with a weak solution of silver nitrate was made. The condition of the eye on the third day was still worse. The eyelids were much swollen. The membranous deposit over the bulbous and palpebral conjunctiva so glued the bulbar and palpebral surfaces together that it was with difficulty that the conjunctival sac could be exposed and bleeding took place when separation was attempted. The cornea was unaffected, except for slight dryness and oedema. Diphtheria was again thought of but negative findings from the smear led us to think of an acute sloughing condition in a debilitated child who had been on a vitamin-deficient patented cereal food diet for months. No anti-diphtheritic serum was

given. All attempts to check the conjunctivitis, to dissolve the membrane or to keep the lids from sticking together by introducing cod-liver oil failed. The general condition was critical before the inflammation of the eye and was more so now. During the fourth night the child commenced having uncontrollable bleeding from the bowels and died an hour later, the diagnosis of the eye condition still being doubtful. Within a fortnight the diagnosis of diphtheritic conjunctivitis came to be regarded as a certainty when a second child in the same house, an elder brother, developed a typical diphtheritic membrane on the fauces and tonsils which showed positive microscopic finding. Serum treatment was given immediately with the usual successful result.

Case 2.—A young villager from Bhulan named Udhwa, aged 24, was admitted to the outpatient department on the 12th March, 1934, complaining of pain and inability to close his left eye.

The patient stated he was well until about three weeks ago when he developed a very severe headache and slight fever for two days. Both fever and headache became better but he started vomiting. He would eat twice a day and invariably vomit soon afterwards. Ten days after the beginning of symptoms, on the 22nd March, 1934, the patient developed some irritation and redness in the left eye. This increased rapidly and a white membrane appeared on the left lower swollen eyelids. The headache continued to the present time although there had been no further fever. Vomiting stopped altogether on the 9th March, three days before admission.

Patient had walked in from his village 14 miles away from Mungeli. He was in good condition. The temperature and pulse were normal. The heart showed no abnormality.

The left lower lid was seen to be everted, an ectropion being present. The everted mucous membrane was covered with a thick membrane, which was grey and surrounded by an area of congestion and hyperæmia. The membrane consisted of a tenacious necrotic slough which could not be removed. The whole remaining conjunctiva was much swollen and red. When an attempt was made at closing the lids the upper eyelid came down striking the membrane of the everted lower one. The cornea was oedematous. The iris was clear. The pupil was moderately contracted and equal to its fellow.

The right eye presented no abnormality whatever.

A smear from the membrane was positive for diphtheria bacilli. Many typical clumps were present.

A smear from the throat was also positive though no membrane whatever was present.

The patient was advised to stay in our isolation ward but this was refused. All treatment was given as a dispensary case.

Treatment.—The patient was given two injections of 5,000 units and three of 2,500 units of antiserum over a period of eight days when the smear became negative. The membranous part of the eye was painted with 1-8,000 mercury perchloride along with drops of zinc sulphate ($\frac{1}{2}$ per cent) and boric acid (3 per cent). The patient was recommended to come into the hospital as his pulse and general condition were not improving. He declined however and returned to his home.

A report has just been received which states that the patient has completely recovered without any traces of scarring or deformity being present. It is considered that a larger number of antitoxic units should have been given.

ENTIRE ABSENCE OF THE UTERUS

By A. F. W. DA COSTA, F.R.C.S.E., D.T.M., L.M.S., V.D.

MAJOR, I.M.D.

Kamptee Road, Nagpur

Mrs. P. S., aged 31 years, a Kayasth by caste, and a resident of Bihar, came under my observation in

August 1934 for trachoma. Her height is five feet one and a half inches and weight ten stones and two pounds, which indicates that she is well built, quite robust, and in good health.

She had never menstruated in her life and was anxious to have something done for her as she was frantically desirous of having a baby, *i.e.*, she was suffering from primary amenorrhœa and that is how the patient was referred to me.

About eight years ago she was in a mission hospital where, she says, under general anaesthesia, she was subjected to a vaginal operation. Nothing however resulted from this operation.

On the 8th August, 1934, I put her on a gynaecological table, made a per vaginam examination and found no sign of even a rudimentary uterus. One could just feel a roughish dimple which I suspect is the scar of the operation which (probably in search of a uterus) she states she submitted to in the Mission hospital, but it is just possible that it might be the position of the absent uterus represented by a rough dimple or depression.

On exposing the external genitalia, one was struck with the entire absence of hair on the pubis, round about the vulva, perineum and anus. The thighs and other parts were quite smooth, and her breasts were well developed but pendulous.

On introducing a duckbill speculum and exposing the vaginal cavity with an elevator the only thing that could be noticed was the dimple I have referred to above. A rudimentary uterus is not an uncommon finding, but the absolute absence of a uterus is rare. The labia and urinary meatus seemed normal, but the vaginal cavity was about one-third the normal size, the remainder with the uterus being absent.

The ovaries and tubes were not palpable, but in a healthy person they usually are hardly perceptible to the fingers. As the patient was of a heavy build, delicate palpation was not easy.

No satisfactory explanation can be given for this abnormality.

FAMILIAL PERIODIC PARALYSIS

By MOHD. YOUSAF KHAN, L.S.M.F.

Sub-Assistant Surgeon, In-charge, Laboratory and Anaesthetist, Civil Hospital, Mullan

AN interesting case of familial periodic paralysis came under my care quite recently and incidentally illustrated the hereditary nature of the disease. As the condition is so rare, a résumé of the main features of the disease may be given.

The disease is seldom seen; only 200 cases have been reported so far. It is characterized by a temporary flaccid paralysis of the muscles of the extremities and trunk with a loss of the deep reflexes and diminished or lost faradic excitability. The paralysis may pass off rapidly or slowly. It is a familial disease—usually confined to males, appearing at puberty and diminishing in frequency after middle age. Pathological observation has so far revealed no cause of the disease. It is considered by some to be a metabolic auto-intoxication.

History of the case.—The patient, a Mahomedan youth, 21 years of age, belonging to the Khichi Rajput agricultural type, came to me on account of his condition. His first attack came on four years ago, when he awoke one morning, unable to move his limbs.

The organs of speech, respiration, deglutition, and excretion were unaffected. The attack lasted two hours and there were no after effects. The patient was not alarmed by his condition, as he had seen his elder brother similarly affected two years previously. Since that date he has had several attacks of varying duration and severity. The exciting cause was attributed sometimes to a rich meat meal, eating of sweetmeats and exposure to cold. The attack usually came on on waking from sleep. The patient is of good physique and there is no sign of other hereditary disease. The patient has never suffered from venereal disease.

Treatment.—Various drugs, allopathic and non-allopathic, have been tried without avail. This spring he had an attack of malaria and was treated with quinine by a colleague. This appeared to diminish the frequency but not the severity of the attacks. At present he is on moderate doses of potassium citrate and kept under observation.

Below is a diagram of the family tree with analysis:—

1. Father of Allah Bux Khan (no. 2) and Allah Ditta Khan (no. 3): was not affected; is dead; name, age, cause of death unknown.
2. Allah Bux Khan: suffered; is dead; did not die of this disease; none of his sons or daughters suffered.
3. Allah Ditta Khan (60 years): son of no. 1; suffered; is dead; did not die of this disease; none of his sons or daughters suffered.

- Male affected.
- Male not affected.
- ⊕ Daughter not affected.
- D. Dead.

4. Ghulam Mohd: daughter's son of Allah Ditta Khan (no. 3); suffered from 17 years to 45; is alive; none of his sons or daughters suffered.

5. Mohd Khan, 24 years (widower).
6. Nur Mohamad Khan, 21 years (unmarried).
daughter's sons of Allah Bux Khan (no. 2); both suffer since the age of 17 years.

7. Hashim Khan, 12 years, brother of nos. 5 and 6; so far not affected.

Sisters of nos. 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12 and 13: not affected yet.

8. Fir Bux: died at 25 years of age; suffered from 18 to 25 years.

9. Ahmad Khan, 22 years; suffering from 17 years of age.

10. Allah Ditta, 20 years; suffering from the age of 18 years.

11 and 12. Mohd Yar, 14 years, and Ramzan, 12 years; not yet affected.

13. Ilahi Bux: died at 7 years of age; not suffered.

Conclusions

1. No deaths have been recorded as due to this disease.

2. The disease is confined to the male sex and is transmitted through the female.
 3. The disease appears at puberty and declines or disappears at about 50 years of age.
 4. The sons of those affected do not suffer.
 5. The daughters of those affected do not suffer but they convey it to their male offspring.
 6. The sisters of those affected do not suffer.
- No form of treatment has as yet been found to have any influence on the condition.

A FATAL CASE OF BRONCHIAL ASTHMA*

By FRANCISO DIAS

Casa Cirurgica, Dramapur, South Goa

S. F., an Indian male, 37 years of age, a clerk in British Africa, consulted me on the 3rd January, 1934, on account of a mild attack of influenza. He had previously had an attack of asthma in 1918 which however had lasted only a few hours and was relieved by a brisk purge. In September 1933, he had an attack of acute bronchitis, during which he suffered from a transient bout of asthma. Later on the patient suffered from dyspepsia and spent three months in a tuberculosis sanatorium as a suspect case. Neither x-ray plates nor an examination of the sputum showed any indication of tuberculosis. He was treated there for asthma with autogenous vaccines made from his sputum. He then returned home feeling quite fit.

The patient consulted me on the 3rd January, 1934, and was treated for bronchitis. On the evening of the 8th January he had a paroxysm of asthma. The usual antispasmodics along with ephedrine and adrenalin were given without avail. On the evening of the 11th in view of its continued recurrence a dose of morphia and atropine was injected. This eased the attack and procured some rest but resulted in oliguria.

The status lymphaticus reappeared on the 12th, the pulse was 130 per minute. Blood pressure—135 to 90, the urine was scanty and albumin was absent. Pituitrin and adrenalin were given to relieve the condition. On the 16th January the asthma had diminished somewhat although the patient complained of exhaustion. Shortly afterwards while changing his dress he was overcome by a paroxysm and died. The post-mortem appearance of the face was that of congestion and cyanosis.

PASSIVE COLLAPSE OF LUNG DUE TO SPONTANEOUS PNEUMOTHORAX

By A. N. DUGGAL, M.R.C.P. (Lond.), D.T.M. & H., D.P.H.
CAPTAIN, I.M.S.

and

J. R. DOGRA, M.D.
CAPTAIN, I.M.S.

A SEPOY, aged 20, admitted on 24th May, 1934, complaining of fever, cough and headache—duration one day.

Patient had no previous illness except a minor injury in the epigastrium a year ago from which he recovered and had been on full duty since.

The patient at the time of admission was tall, thin, with bright eyes and long eyelashes. Physical examination revealed nothing abnormal except a few scattered râles in both lungs. Blood examination showed normal white blood cell and differential counts. Urine normal. The nature of the temperature led to various laboratory examinations for malaria,

enteric, Malta and typhus-like fevers. These tests were negative, thus excluding the above conditions. The Wassermann reaction was negative. Repeated examination of sputum (direct smears, antiformin method and guinea-pig inoculation) showed absence of *B. tuberculosis*. The fever and cough continued for one month while symptomatic treatment was given. On 22nd June, 1934, the patient complained of severe dyspnoea, incessant cough with a large amount of purulent sputum. Physical examination then revealed deficient air entry into the right lung without any change in percussion and vocal resonance; distant bronchial breath sounds with few râles were audible in the right interscapular region. There were no physical signs suggestive of a cavity. Skiagram (a) showed presence of pneumothorax in the right chest with extensive consolidation of entire lung and suggestion of a cavity at the apex.

The temperature remained continuous thereafter with profuse expectoration which was blood-stained at times.

Skiagram (a). Shows right-sided pneumothorax, with consolidated lung and a cavity at the apex.

Skiagram (b). Shows presence of fluid in the right side in addition to (a).

On 1st July, 1934, typical signs of 'open' pneumothorax, i.e., tympanitic note, ringing-coin percussion, amphoric breathing, metallic and tinkling consonances developed. The apex beat of the heart was in its normal position. The patient's condition got worse with marked toxæmia and emaciation. The skiagram (b) now showed presence of fluid in the right chest.

* Rearranged by Editor.

Five ounces of serous fluid was aspirated. Examination showed absence of *B. tuberculosis* and other organisms with lymphocytes and a few polymorphonuclears. Patient died on 4th July, 1934.

Unfortunately a post-mortem examination could not be arranged.

Points of interest

1. Spontaneous pneumothorax was obviously due to the rupture of a cavity in the right apex. Its location and the age of the patient are suggestive of its being tuberculous in nature.

2. Pneumothorax started as one of 'closed type' with complete consolidation of collapsed lung, later becoming one of the 'open type'.

3. Physical signs of the cavity were masked by the presence of pneumothorax and entire consolidation of the lung.

4. Sputum and pleural fluid showed absence of tubercle bacilli.

5. Apex beat showed no alteration in position; this was possibly due to a fixed mediastinum.

We wish to thank Lieut.-Colonel J. F. James, I.M.S., Officer Commanding, C. I. M. Hospital, Razmak, for his advice and permission to make use of the notes and skiagrams.

A LARGE OVARIAN CYST

By S S HAYARE, MB, BS.

Chief Medical Officer, The Good-Fellow Hospital
Palanpur (N. G.), India.

A PATIENT, S R, about 35 years of age, came to this hospital on the 20th July, 1934, on account of a huge tense abdominal swelling. Although she weighed 160 pounds, her face and extremities were emaciated; otherwise her condition was fairly good. She had given birth to two children in her early married life and

Ovarian cyst

Fig 1—S R, before operation

thereafter the abdomen commenced to enlarge over a period of fifteen years. After a thorough investigation of the case it was decided to be an ovarian cyst of the right side. She was operated on on the 21st July and 60 pounds of a thick glairy fluid was withdrawn by tapping. The remainder of the fluid and the cyst itself were then removed. The total weight of the cyst and contents was 80 pounds. After the operation the

patient was put on nourishing diet and tonics. She was discharged cured on the 19th August. The outstanding features of the case were, the size of the cyst, its duration (15 years) and the vitality of the patient

Ovarian cyst

Fig 2—S R after operation

in withstanding the shock of the operation. The photographs of the patient before and after operation illustrate more vividly her condition.

DELIRIUM AFTER QUININE ADMINISTRATION

By JAGADISH CHANDRA DUTTA, L.M.P.

Rajah Ali Tea Estates, Hoogrijan P. O., Assam

A PATIENT named Jatiram, aged 25 years, was admitted into this hospital with hyperpyrexia. The temperature was 105.4°F. The liver and spleen enlarged; bowels not constipated; heart regular. The patient had no other complaint except high fever. No cerebral symptoms, not even a headache during the fever since his admission. I applied a cold compress to the head and sponged the whole body with cold water. I gave him a diaphoretic mixture every two hours and, after taking six doses, his temperature came to 100.2°F. I now tried quinine five grains with liquor arsenicalis. After taking the quinine he suddenly became delirious and unconscious with severe dyspnoea. He had no chest complaint and had no history of rheumatism. There was no remission of temperature after taking the quinine. I now tried a diaphoretic mixture with bromide. After taking four doses, all the severe symptoms disappeared and the temperature came down to 99.6°F. I now again tried quinine in small doses (two grains). After half an hour the patient was attacked with the same symptoms. This time he vomited a lot of bile mixed with mucus and was very restless. By this time his condition rather alarmed me. I again tried diaphoretic mixture with bromides. After taking six doses his symptoms cleared up and the temperature came down to 99°F. After eight doses his temperature came to normal, 98.4°F. I continued the mixture every four hours for three days and the case was discharged quite fit and well. I did not again administer quinine. It is remarkable that the patient could not bear even small doses of quinine although suffering from hyperpyrexia with enlarged spleen and liver; the diaphoretic apparently alleviated the more urgent symptoms.

I am grateful to my medical officer, Lieutenant-Colonel F. J. Palmer, for his kind permission to publish this case.

Indian Medical Gazette

JANUARY

THE TOXICITY OF ATEBRIN

THE reception accorded by the medical profession, and to a less extent by the general public, to any new specific seems to be governed by an unalterable law; there are three distinct stages in this reception—the stage of acclamation when it is hailed as the *therapia magna sterilans* and as the last word in the treatment of the disease in which it is used, the stage of abuse when, rightly or wrongly, it is compared disadvantageously with older, established forms of treatment and unfavourable by-effects are attributed to it, and finally the stage when its limitations are defined and it either takes its place in the pharmacopœias of the world or is discarded.

The frailty of human nature and a tendency to exaggerate are undoubtedly responsible to some extent for the sharp contrast between the first and second stages, but it is not necessary to emphasize these, as the whole process is as natural as the swing of the pendulum. We will take salvarsan as an example. One heard practically nothing of its 605 unsuccessful predecessors; naturally, nobody was going to write detailed articles reporting that they had tried a new drug for syphilis which was not very successful and was on the other hand rather toxic; even if they had, no editor of a medical paper would have published them. The information gained by such trials is of scientific value and should be recorded somewhere, but it has no 'news-value', as nine hundred and ninety-nine out of every thousand of the readers of the journal will never have heard of the substance. First reports must therefore necessarily be good reports. Other people use the drug and writers vie with one another in reporting larger series of cases, and better and better results, until all that is good has been said about the drug, and to praise it further is plagiarism. Then the sceptics have their chance; they may have come into the field rather late, they have read the early reports, perhaps not too critically, and have obtained an exaggerated idea of the value of the drug; they are disappointed in the results that they obtain, and they say so, emphasizing the shortcomings of the drug rather than its qualities; others follow suit. But we need not follow this hypothetical case any further.

Atebrin is at present in the process of going through these stages. It is, we imagine, now coming to the end of the second stage. It has been subjected to a very considerable amount of criticism during the last year, and is on the

whole coming out of it remarkably well. We propose to confine the present discussion to the question of its toxicity.

Toxicity is a relative term; one cannot just say that a drug is toxic, or not toxic. There are two qualifiable factors concerned, the drug and the patient. It is obvious to everybody that, whereas one grain of a drug may be non-toxic, it is quite possible that ten grains may be very toxic indeed, but it is perhaps not so fully realized that individual susceptibility is liable, in the case of certain drugs, to a ten-fold variation; that is to say the maximum tolerated dose may be ten times as great as the minimum lethal dose. The toxicity of a drug should therefore be expressed as a curve, with the doses as the ordinates and the percentages of individuals of a given population showing toxic symptoms, as the abscissæ, but in order to draw this curve a very considerable experience with a drug is necessary. We are now approaching the time when the combined experience of a number of workers has given us sufficient data to draw such a curve with reference to atebtrin. We do not propose to do this, nor to review the literature on the subject, which is now considerable; there are however in this number three papers in which the subject of the toxicity of atebtrin is introduced and in one of these the subject is discussed at some length.

Williams and Bhattacharyya gave preventive courses consisting of one gramme of atebtrin spread over five days (to adults and proportionate dosage to children) to each of 234 tea-garden coolies, and later they administered fifty treatment courses corresponding to a total adult dosage of 1.5 grammes of atebtrin spread over five days to those individuals who developed malaria; they summarize their experience in the words 'ill-effects were very few and not at all dangerous'; these ill-effects consisted of yellow discoloration of the skin in three cases, giddiness in three, slight abdominal pains in one, and anorexia in one. These writers distinguish between the ill-effects caused by atebtrin and those caused by plasmochin; although in every case the course of atebtrin was followed by one of plasmochin, only two patients complained of abdominal pain during the latter course.

Newman and Chalam adopted two separate plans of treatment; in one the course of plasmochin followed the course of atebtrin, and in the other the drugs were given together. They do not attempt to distinguish between the ill-effects caused by atebtrin and those caused by plasmochin; the course of atebtrin consisted of an adult dosage of 1.5 grammes spread over five days and that of plasmochin of 0.15 gramme similarly spaced; of the 258 persons that received the drugs separately, ill-effects were reported in 15—slight discoloration of the skin and gastric pains in five and seven, respectively,

and in three severe gastric pains and yellow pigmentation of the skin. They remark 'that none of these symptoms was of any consequence'.

There is a very close parallelism between these two reports; in the first, by-effects are noted in 10 out of 248 treatments and in the second in 15 out of 258. In the former a slightly lower dosage was administered to the majority of the patients and this may be taken to account for the lower incidence of by-effects, but considering the two series together one concludes that unimportant by-effects may be expected in about five per cent of persons to whom the usual course of atebirin followed by one of plasmochin is given.

On the other hand, the experience of Newman and Chalam with the combined administration of atebirin and plasmochin does seem to indicate that one enhances the toxicity of the other, as, when the two drugs were given together to seventy-six persons, sixteen of these exhibited untoward symptoms; in one case there was 'severe gastric pain, vomiting and slight collapse'.

Chopra and Chaudhury have reported eleven cases in which very definite and temporarily-serious symptoms have followed the use of plasmochin, or atebirin and p. smochin. The majority of the patients in this series either had taken these drugs on their own initiative without any medical advice, or had in the first place been advised by their doctor to take them and had then continued to do so without following his advice regarding dosage, but we are afraid that there were other instances in which it was quite obvious that the medical man in attendance had a very incomplete appreciation of the action and knew nothing of the dangers of the promiscuous administration of these two drugs. These two writers also suggest that atebirin may have some influence in increasing the toxicity of plasmochin.

Green reporting his experience in Malaya said that there had been no complaints in a series of 600 rubber-estate coolies receiving the 'usual' course of atebirin, a maximum total dose of 1.5 grammes, that by-effects, mostly mild, were noted in 10 per cent of hospital patients receiving a seven-day course (2.1 grammes in adults) and that seven out of twenty patients taking a more intensive course of 2.8 grammes over a period of seven days showed by-effects.

The commonest by-effect of atebirin administration is yellow discoloration of the skin and conjunctiva, and though it is the least important of the by-effects it has given rise to more misunderstanding than any of them. Patients themselves, unless they have been warned, very naturally associate this yellow discoloration with jaundice, but it is surprising that a large number of medical men also entertain this misconception, and we have

repeatedly heard references made to the toxic action of atebirin on the liver; there is, as far as we know, no evidence that atebirin has any such toxic action. One point that seems to give rise to suspicion is that this yellow discoloration is only noted occasionally and that when it does occur it is sometimes accompanied by other symptoms. The assumption is that the yellow discoloration is more noticeable in those patients who are not excreting the drug as rapidly as the normal person; probably therefore it is in these people that other by-effects would most commonly occur. If this is the case, then the yellow discoloration should prove a valuable danger signal, suggesting that the drug must not be continued beyond the usual dosage, and, if we are going to attribute any interaction between the two drugs (and evidence in this connection is accumulating), that plasmochin should be withheld, for a time at any rate.

Other by-effects that have been attributed to atebirin are hæmoglobinuria, gastric pains, headache, anorexia, mental depression and excitation and in some cases even temporary psychoses. Nearly all the by-effects reported have been of a temporary nature and few have been serious. In the case of the more serious ones, *e.g.*, hæmoglobinuria, closer investigation has nearly always shown that plasmochin was also being administered.

When a new drug is being used there is a tendency to attribute to the ill-effects of this drug any deviation from the ordinary course of the disease, and, in the case of the inexperienced worker, even the normal symptoms of the disease; in many instances the so-called ill-effects of atebirin can be accounted for, thus, but it is, of course, possible that certain persons will show an idiosyncrasy towards it, and the few cases of mental disturbance that have been reported from Malaya, where this drug has been used very extensively, may be examples of this personal idiosyncrasy. This is a question that time and further experience will answer, but, in view of the smallness of the number of such instances in the very considerable experience that has been accumulating during the last four years, we may conclude that the more serious by-effects of atebirin are very rare.

Another problem that is awaiting solution is whether or not atebirin and plasmochin given together, or within a short space of time, produce more by-effects than each drug given separately. There is a considerable amount of clinical evidence to show that combining the drugs does increase their toxicity, though it is not conclusive, and it is quite possible that an innocuous combined course may yet be devised. Further, it should be remembered that as yet there is little evidence to show that plasmochin enhances, to any marked extent, atebirin's action on the schizonts of any of the

plasmodia. Therefore the addition of plasmo-chin will not accelerate the patient's recovery, nor reduce the chances of a relapse, and only in special circumstances is it necessary to give it.

We may conclude by saying that accumulated experience suggests that atabrin, in the ordinary

curative dosage of 0.1 gramme three times a day for five days (for adults and proportionately for children), will not cause serious symptoms in—shall we say—one in every thousand individuals to whom it is given, but that a small percentage—from one to five—of persons will experience unimportant by-effects.

Commentaries

[Under this heading we propose to publish, from time to time, commentaries and detailed reviews of important reports, books and papers, sent to us by contributors.

Colonel Stott's is an example of the type of contribution that we hope to publish: next month a review of *Recent Advances in Ophthalmology*, by Lieutenant-Colonel R. E. Wright, C.I.E., I.M.S., Superintendent, Ophthalmology Hospital, Madras, will appear in this section.

We wish to draw the attention of principals of teaching institutions in India to the educative value of such contributions, with the hope that they will send us similar commentaries.—EDITOR, I. M. G.I

THE ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION'S CLASSIFICATION OF MENTAL DISORDERS

ABILITY to classify clearly and to define rightly forms a high road to increased knowledge of the problems to be surveyed within the range of any given subject under consideration. Classification and definition become easier in proportion to the knowledge available concerning the subject, to the specialized skill of those engaged on the work, and to the time and interest taken therein.

As regards the mental disorders, knowledge is still in the stage of evolution, wherefore, classification is unsatisfactory, and few authorities have agreed upon a provisional working scheme. The ætiological factors of mental disease are at present too ill known to provide a sound basis of classification. Symptomatology, as a localizing agent in the organ of the mind, is far less defined than in the case of other body organs. Morbid anatomy, too, provides no adequate help for although it is true that the grosser defects of the brain are revealed as yet we possess insufficiently delicate procedures with which to estimate rightly those naked-eye and histological changes which occur in mental disease. Nor has psychopathology, still in its infancy, yet provided us with sufficient data for a satisfactory classification.

It is therefore particularly fortunate that the Royal Medico-Psychological Association has presented the medical profession with a practical scheme of classification in two parts which are intended to be used in conjunction with one another.

Part I presents the actual classification, being based on clinical pictures or syndromes of

mental disorder with which all psychiatrists are familiar, whilst part II schedules those ætiological or associated factors in mental disease which are so far generally recognized.

This scheme has not been hurriedly evolved, nor by individuals without considerable practical experience of mental disease. The sub-committee responsible for it has laboured throughout four years from 1929, and consisted of no less than nineteen mental specialists. These included representatives from four London teaching hospitals, the School of Medicine for Women, the Post-graduate College, the Edinburgh and Welsh Universities, together with a commissioner of police, so that each practical aspect has been well and truly considered.

The scheme is so helpful in its ease of application, so elastic in its provision for future extension and so stimulating towards the fuller investigation of the cause of each individual case of mental disorder that it appears worthy of the widest adoption.

The two parts of the classification now follow. Thereafter a series of comments in fuller explanation of the several groups of part I is appended. The original communications were published in the *Journal of Mental Science* of April 1932 and of October 1933.

The classification is perhaps rendered of greater simplicity if the major head under 'D' of part I were described as

D—*Systematized delusional psychosis*.

(a) Paranoia, (b) Paraphrenia, instead of

D—*Psychopathic constitution and paranoia*.

(a) Pathologic constitution, (b) Paranoia; for systematized delusions, which form a readily-recognized clinical syndrome, find a convenient pigeon-hole in this group of mental disorder. Paraphrenia which is a half-way link with dementia præcox may be placed in either group, though as delusions are prominent it is perhaps better classed with paranoia. If paraphrenia is placed in the above relationship with paranoia, the paranoid type of dementia præcox in which delusions occur becomes the connecting link with group C. The several grades of paraphrenia are well described in Major Lodge-Patch's recently-published excellent *Textbook of Mental Disease* (Baillière, Tindall and Cox)

which renders this obtuse speciality understandable and indeed enjoyable alike to the student and to the practitioner of general medicine.

THE CLASSIFICATION OF MENTAL DISORDERS PART I.—CLINICAL CLASSIFICATION

(To be used in conjunction with part II, *Ætiological Factors*)

- A. *Oligophrenia* (amentia, mental deficiency).
 - (a) Idiocy.
 - (b) Imbecility.
 - (c) Feeble-mindedness (moron).
 - (d) Moral deficiency.
- B. *Neuroses and psychoneuroses*.
 - (a) Exhaustion states (including true neurasthenia).
 - (b) Anxiety states.
 - (c) Compulsions, obsessions, and phobias.
 - (d) Hysteria.
 - * (c) Mixed and other forms.
- C. *Schizophrenic psychoses*.
 - (a) Dementia præcox.
 - (i) Simple type.
 - (ii) Hebephrenic types.
 - (iii) Katatonic types.
 - (iv) Paranoid types.
 - (b) Paraphrenia.
 - * (c) Other forms.
- D. *Psychopathic constitution and paranoia*.
 - (a) Pathological constitution.
 - (b) Paranoia.
- E. *Affective psychoses*.
 - (a) Manic-depressive psychosis (cyclothymia).
 - (i) Elation.
 - (ii) Depression.
 - (iii) Stupor.
 - (b) Involution melancholia.
- *F. *Confusional states*.
- G. *Epileptic psychoses*.
- H. *General paralysis*.
- *I. *Other psychoses associated with organic brain disease*.
- *J. *Dementia*.
- *K. *Undetermined types*.

PART II.—ÆTIOLOGICAL (OR ASSOCIATED) FACTORS

- 1. *Heredity* (7).
 - * (a) Psychotic.
 - (b) Epileptic.
 - * (c) Neurotic.
 - (d) Alcoholic.
 - * (c) Various organic nervous diseases.
 - * (f) Endocrine disease.
 - (g) Tuberculous.
- 2. *Deprivation of special sense* (2).
 - (a) Sight.
 - (b) Hearing.
- 3. *Critical periods* (4).
 - (a) Puberty.
 - (b) Adolescence.
 - (c) Climacteric.
 - (d) Senility.
- 4. *Child-bearing* (3).
 - (a) Pregnancy.
 - (b) Puerperium (not septic).
 - (c) Lactation.
- 5. *Mental factors* (3).
 - (a) Previous attacks of mental disorder.
 - * (b) Sudden stress.
 - * (c) Maladjustments of
 - (i) Social life.
 - (ii) Sex life.
- 6. *Physiological disturbances* (3).
 - (a) Malnutrition.
 - (b) Privation.
 - * (c) Exhaustion.
- 7. *Trauma* (4).
 - * (a) Injuries.
 - * (b) Operations.
 - (c) Sunstroke.
 - (d) Electric shock.
- 8. *Toxic factors* (11).

A. Chemical.

- (a) Alcohol.
- * (b) Narcotic drugs.
- * (c) Mineral poisons.
- * (d) Other poisons.

B. Infective.

- (a) Syphilis.
- (i) Congenital.
- (ii) Acquired.
- (b) Puerperal fever.
- (c) Influenza.
- * (d) The specific fevers.
- (c) Tuberculosis.
- * (f) Focal sepsis.
- * (g) Other infections.

*C. Metabolic.

- *9. *Deficiency diseases*.
Pellagra, beri-beri, etc.

*10. Diseases of the nervous system.

11. Diseases of other systems (6).

- * (a) Hæmopoietic.
- * (b) Cardiovascular.
- * (c) Respiratory.
- * (d) Gastro-intestinal.
- * (e) Genito-urinary.
- * (f) Endocrine.

12. No factor ascertained.

13. No history obtained.

Notes :—

1. Where a patient is suffering from a syndrome which is not fully described by the clinical group heading in part I the complete details should be specified. For example, a case of Korsakov's syndrome should be returned as 'confusional state' (Korsakov's syndrome), and if excessive drinking was known to be the cause, the complete classification expressed in symbols, for statistical purposes, would be F. (Korsakov's syndrome), 8, A, (a).

2. The heads in part I which are likely to require further specification are marked with an asterisk (*)—and in these cases the precise ætiological factor is to be specified when known. Similarly certain headings in part II are so marked and in these cases the precise ætiological factor is to be specified when known.

3. For example, a psychosis due to cerebral tumour would appear as I., 10 (cerebral tumour); or a case of depression following influenza and with a family history of manic-depressive psychosis would appear as E., (a), (ii), 8, B, (c) and 1, (a) (manic-depressive).

COMMENTS AND EXPLANATORY

A. *Oligophrenia* (amentia, mental deficiency)

A condition of 'small' (ὀλιγος) 'minds' (φρον) from arrested or incomplete development whether arising from inherent causes, or induced by disease or injury. Etymologically 'amentia' ('absence of mind') is misleading. Amentia also was first used for 'confusional insanity', and is so used in the Norwegian, Dutch, Italian, and Viennese classifications. The term oligophrenia should therefore replace the word amentia in the sense of this classification. The definitions of the four sub-groups are those of the Mental Deficiency Acts (England) of 1913. The classification of the first three states consists in a useful grading of mental capacity, (a) 'idiots' being without intelligence and unable to protect themselves against common physical agents, (b) 'imbeciles' having rudimentary intelligence, insufficient to

manage themselves or their affairs and incapable of being taught to do so, whilst (c) the 'feeble-minded' possess yet a larger amount of intelligence but they require care, supervision and control for their protection and appear permanently incapable of receiving proper benefit from instruction in ordinary schools. Sub-group (d) *moral deficiency* corresponds to what Tredgold calls a 'moral imbecile', i.e., one who has a permanent moral defect from an early age with strong vicious or criminal propensities, and on whom punishment has had little or no deterrent effect. In all cases the defect exists from birth or from an early age.

B. The neuroses and psychoneuroses

No differentiation is made between these two conditions. Either term is preferred to the expression 'minor psychosis'.

(a) *Exhaustion states* (including neurasthenia). This should designate abnormal mental states characterized essentially by mental or motor fatigability and irritability. The word neurasthenia was rejected since its war-time use as a dumping ground for all sorts of mental disorders. Freud also uses neurasthenia in a restricted sense to signify the exhaustion following masturbation. The expression 'exhaustion states' conveys a very definite meaning, and indicates a fairly clear clinical condition.

(b) *Anxiety states*.—This group includes the symptoms commonly exhibited by generalized fear.

(c) *Compulsions, obsessions and phobias*.—Phobias have been separated from the anxiety states because of a fundamental difference between the vaguer, more indefinite and generalized fears of the latter, and the attachment of fear or anxiety to some definite object or situation in the former.

Obsessive ideas persist in intruding into consciousness whatever the patient may be thinking of. There is no conscious wish concerning the production of the obsession.

(d) *Hysteria* is a faulty reaction to environment, characterized by a variety of (1) motor symptoms, (2) sensory symptoms and (3) mental symptoms.

C. Schizophrenic psychoses

By derivation schizophrenia (gk.) means a splitting, cleavage or rending asunder of the mental functions. This syndrome includes cases which show *remissions*, and even rare *recoveries*, in addition to the classical type which results in *progressive deterioration* to profound dementia.

(a) *Dementia præcox*.—Etymologically signifies precocious (i.e., juvenile or adolescent) dementia. The will and emotions are especially affected.

There are four main clinical groups.

(i) *The simple type*.—The powers of attention of interest and of affection and of the senses gradually fail. An apathetic state or inactive vegetable existence develops, often with peculiar behaviour, but *without* expression of delusions or of hallucinations.

(ii) *The Hebephrenic group*.—Hebe was a Greek Goddess of youth. Prominent features of this group are tendencies to silly laughter, grimaces, and mannerisms with grotesque ideas and erratic behaviour.

(iii) *The Katatonic group* shows prominently a negativistic resistive attitude, which may develop into the performance of the exact opposite of any useful action suggested, but the patients become very suggestible to perform futile actions. The third symptom is stereotyped behaviour in attitude, movements or speech. A fixed rigid attitude may be assumed for hours on end.

(iv) *The paranoid group*.—Delusions (whence the name paranoid), usually of persecution or of grandeur, or hypochondriacal, together with hallucinations of the various special senses, are usual. The course tends to be rapid with early dementia; whilst the above types are classical, cases and symptoms are often mixed.

(b) *Paraphrenia* resembles both paranoid dementia præcox and paranoia. But both emotional and volitional disorder is absent or slight in paraphrenia, as compared with paranoid dementia præcox, whilst the condition progresses to dementia, as compared with the very prolonged course of paranoia, where intelligence of a high order typically remains.

(c) Other forms.

D. Psychopathic constitution (including paranoia)

(a) *Psychopathic constitution*.—This group includes a large number of pathological personalities amongst criminals, tramps, litigators, queer people, anti-this and anti-that, sex perverts, most drug addicts, mattoids, agitators, etc.—the prison psychoses.

(b) *Paranoia*.—In paranoia or delusional insanity, the delusions are of insidious development. Though different authorities describe various cases, some terminating in dementia, within the limits of this syndrome, the Royal Medico-Psychological Association considers that paranoic conditions which do not end in intellectual impairment should be separated from the schizophrenic psychoses. Hence this group is defined as showing no mental impairment, and as being without hallucinations.

E. Affective psychoses (i.e., the psychoses of the affections or emotions)

These are characterized by defect of some of the higher functions (will, attention, concentration and judgment, and by the

predominance over them of the lower level automatic associations).

(a) *Manic-depressive psychosis* (cyclothymia). (1) Elation and excitement and motor activity. (2) Depression, misery and inactivity. (3) Stupor.

(b) *Involucional melancholia*.—This group comprises the slowly developing depressions of middle life and of later years characterized by (1) worry, (2) insomnia, (3) uneasiness, and (4) agitation. The Royal Medico-Psychological Association considered that these involucional states were more allied to manic-depressive insanity than to the schizophrenic conditions. States of depression in arteriosclerosis should be included in group I.

F. Confusional states

The title is self-explanatory.

G. Epileptic psychoses

This group includes only what is known as 'essential' epilepsy with psychosis. Obviously however an epileptic may remain sane or may develop some other form of insanity such as manic-depressive psychosis. The group will undoubtedly be subdivided as knowledge progresses. Cases of organic brain disease, with seizures of any kind, are not to be included.

H. General paralysis

This forms a well-recognized group though purists may not agree with the diagnosis as sometimes made, but our knowledge is insufficiently advanced to permit of any alteration. Cases of cerebral syphilis are excluded.

I. Other psychoses associated with organic brain disease

That is other insanities with gross brain lesion, e.g., arteriosclerosis of the cerebral arteries resulting in premature senility, cerebral hæmorrhage and thrombosis and cerebral tumours. It was felt that there was no need to separate off more than the syphilitic conditions.

J. Dementia

This group does not include the dementias where the original condition is known.

K. Undetermined types

This group was retained for conditions which could not be classified under any of the divisions A to J.

Medical News

THE FACULTY OF TROPICAL MEDICINE AND HYGIENE, BENGAL

THE following students are declared to have passed the L.T.M. Examination, Session 1934.

Passed

(Arranged in alphabetical order)

1. Dinabandhu Basu, L.M.F., Private Practitioner.
2. Sham Singh Bedi, L.S.M.F., General Duty, Mayo Hospital, Lahore, Punjab.
3. Nagendra Nath Bhadury, L.M.F., Assistant Medical Officer, Lakwah Tea Estate, Assam.
4. Sudhir Chandra Bhattacharjee, L.M.F., Private Practitioner.
5. Ramanlal Desai, L.C.P.S. (Bom.), Medical State.
6. Krishna Kishore Dutt, L.M.F., Private Practitioner.
7. Prakash Nath Ghose, L.M.F., Assistant Medical Officer, Dhullia Tea Estate, Assam.
8. Anil Kumar Ghosh, L.M.P. (Bihar and Orissa), Private Practitioner.
9. Promodendu Gupta, L.M.F., Private Practitioner.
10. Ganpaya Shambaya Kote, L.C.P. & S. (Bom.), Private Practitioner.
11. Anant Ram Luthera, L.S.M.F. (Punjab), In-charge, Canal Dispensary, Muridke, Sheikhupura.
12. Sachindra Kumer Mitra, L.M.F. (Bengal), Tongani Tea Estate, Darrang (Assam).
13. Sreepati Bhushan Nath, L.M.F., Private Practitioner.
14. Subhusamy Padmanabhan, L.M.P., Private Practitioner.

15. Kantilal Maneklal Shah, L.C.P.S. (Bom.), Private Practitioner.
16. Popatlal Chandulal Shah, L.C.P.S. (Bom.), Private Practitioner.
17. Ramanlal Ghelabbai Shah, L.C.P.S. (Bom.), Hony. S. M. S. Officer at Civil Hospital, Surat.
18. Ram Lal Sharma, L.S.M.F. (Punjab), Medical Officer, Anand Garh, Sheikhupura.
19. Budh Singh, L.S.M.F. (Punjab), Private Practitioner, Rawalpindi.
20. Pritam Singh, I.M.D., Government of India.
21. Saubhagyachandra Girjashanker Trivedi, L.C.P.S. (Bom.), Private Practitioner.

PUNJAB MEDICAL COUNCIL

THE following is an extract from the summary of the proceedings of the meeting of the Punjab Medical Council held on the 10th November, 1934.

1. Decided that a panel of members be appointed annually as visitors for the various medical examinations held in the province and the following be appointed as visitors for one year:—

- (1) Lieut.-Col. J. J. Harper-Nelson, I.M.S.
- (2) R. B. Dr. Maharaj Krishna Kapur.
- (3) Dr. Mirza Yaqub Beg.

2. The Council resumed consideration of the adjourned case of Mr. Sundar Das, L.M.P., who it was alleged had resorted to advertising his practice. He was called upon to appear before the Council personally but did not appear. The Council decided that his name should be removed from the register for a period of three years.

3. Decided that the representation of licentiates on the Punjab Medical Council should remain as it is at present.

4. Court judgments in the following cases of bogus doctors were recorded and it was ordered that in future the information of the conviction of such bogus practitioners should also be sent to the Director of Information Bureau for publication :—

A. H. Arif Asfani of Lahore, fined Rs. 150.

Offence 'indicated letters M.D. after his name'.

S. M. D. Kazim of Rewari, fined Rs. 150. Offence 'declared himself a registered medical practitioner while he was a quack'.

5. The request of the Principal, Ludhiana Medical School (a private institution for male students), asking for recognition of his school and also the report of Lieut.-Col. Amir Chand recommending that the first professional examination for the present be recognized was considered, and the Council resolved that the opinion of the legal remembrancer be sought in the matter as to which body is competent to deal with the recognition of the first professional examination of the school and the president be authorized if so advised by the legal remembrancer to appoint any member of the Council to visit the school and report.

6. Resolved that the qualification of 'Diploma in Laryngology and Otology' (granted by the Royal College of Physicians of London and the Royal College of Surgeons of England) be brought on to the schedule of 'additional qualifications'.

QUARTERLY BULLETIN OF THE HEALTH ORGANIZATION OF THE LEAGUE OF NATIONS

THE September number of the *Quarterly Bulletin* that has just appeared indicates the range of subjects which come within the purview of the Health Organization of the League of Nations.

The malariologist and the public-health worker in countries in which malaria is an important cause of morbidity will find considerable interest in a report on the efficiency of totaquina in the treatment of malaria. Totaquina, the name given to a standardized mixture of the total alkaloids of cinchona bark, can be produced at a much lower cost than the salts of quinine, which have been used almost exclusively in the past. The report, which has been prepared by William Fletcher and E. Pampana, deals with observations made in several countries; these observations indicate that there is little to choose between totaquina and the salts of quinine in so far as their efficiency in the treatment of malaria is concerned. A second article of interest to the malariologist is written by Swellengrebel and Nykamp, and contains some further observations on the bionomics of *Anopheles maculipennis* in Holland.

Senator Lindhagen, a former Mayor of Stockholm, contributes an illustrated account of the Stockholm Garden Settlements, which cannot fail to interest the many people concerned in town planning, building schemes and the question of housing generally.

A report on the standardization of vitamins gives the results of the Second Expert Conference which was held in London in June of this year. The Conference was held under the auspices of the Permanent Commission for Biological Standardization of the League's Health Organization. The question of vitamin standardization is one of considerable practical importance at the present time.

Nutrition workers will find useful material in an article entitled 'The Effects of the Economic Depression on the Population of Vienna', by Gotzl, Kornfeld and Nobel. Prolonged unemployment appears to have had deleterious effects on the physical condition of the unemployed and their families in Vienna, but the great practical difficulties, inherent in investigations of this kind, in obtaining unequivocal data are fully recognized. They are in fact, well described in the report.

LEAGUE OF NATIONS' EASTERN BUREAU: SECOND INTERNATIONAL COURSE IN MALARIOLOGY, 1935

WE have now received a notice regarding the second of the series of international malaria courses to which we referred in our last issue; this notice is reproduced below.

We anticipate that the number of applications for admission to this course will far exceed thirty—the number that will be accepted; we therefore urge upon our readers the necessity of making early applications. At the same time we would remind them that the malaria courses are not organized for private individuals anxious to add to their academic qualifications, but for practical malariologists employed by governments, municipalities, railways and commercial organizations.

At the first malaria course, India was not well represented (from a numerical standpoint only—actually, we have learnt from a private source, our candidates were amongst the most proficient), and it is obvious that her importance in the Eastern sphere entitles her to more than the three seats she occupied last year. We hope this year that the number and suitability of the applicants from this country will lead to their occupation of a much larger proportion of the seats.

It has long been a matter for comment that the Malaria Commission of the Health Committee of the League of Nations, in its enquiries into malaria, and particularly in its recommendations for the control of the disease, had not been able to take into consideration the situation in the Far Eastern countries and the experience gained there in fighting the disease. There has also been a notable gap in the international malaria courses arranged by the Health Organization in that, while such courses have been held in European countries—London, Paris, Hamburg, Rome—with practical work in Spain and Yugoslavia, it has not been possible to arrange for these courses in the East.

This was brought forcibly home to the Secretary of the Malaria Commission during his visit to Far Eastern countries in 1931-32. He found that the problem was quite different in many respects from that which confronted European administrations. Its scope and nature were much greater, the attack by anti-mosquito control was different, the economic and social conditions of the population did not resemble those of European countries, nor was the system of health administration the same. As a result of such differences malariologists trained in Europe, when they come to take up duty in Eastern countries, are not acquainted with the technique nor fully equipped with that local knowledge of the problem which is essential if it is to be controlled. On the other hand, it has been impracticable for medical officers engaged in work in the East to be spared for the time necessary to attend international malaria courses in Europe, even if the cost of travel did not form a bar.

This need for international training and exchange of experience is very clearly indicated in malaria because of the essentially local character of the problem. This means that expert knowledge of the subject can only be obtained by a study of its effects in several countries. The League, in approving the proposal to organize international malaria courses in the Far East, has kept this in mind and in consequence the arrangements for the Eastern course will provide that the field instruction be carried out in a country other than that from which the students have come while, in addition, three experts from overseas countries will be included among the lecturers.

After much discussion of the question with administrative and other health authorities in the East, the League concluded that Singapore was the logical place to hold such courses. This decision was influenced to some extent by the fact that Singapore was the headquarters of the Eastern Bureau of the Health

Organization and that it also possessed a well-equipped medical school recognized by the General Medical Council of Great Britain.

The League has now organized a yearly course of theoretical and practical training in Singapore and Malaya making use of the wealth of experience of the disease in that and in the neighbouring countries in which field study will be carried out. The technical course for 1935 is in the hands of a committee consisting of Prof. E. W. Walch, Professor of Hygiene in the University of Batavia, Dr. C. L. Park, Director of the Eastern Bureau, League of Nations, Prof. J. C. Tull, Professor of Pathology, King Edward VII College of Medicine, Acting Principal of the College, and Prof. B. A. R. Gater, Professor of Biology in the King Edward VII College of Medicine. The administrative duties will be carried out by the Eastern Bureau.

The object of the courses is to complete the training of medical men who are engaged, or propose to engage, in anti-malaria work. They will thus be of interest not only to governments and municipal authorities, but also to all medical men practising in Eastern countries, particularly those engaged in estate work.

Facilities will also be provided for experienced malariologists to pursue individual research during the period of the courses, and at other times by arrangement with the King Edward VII College of Medicine.

There will be three distinct stages to each course:—

- (1) A preliminary revision course.
- (2) Theoretical and laboratory studies with practical demonstrations.
- (3) Practical field studies.

The preliminary revision course is designed for students who have a limited practical experience of malaria; and those who may wish to revise the principles of hæmatology, protozoology and entomology, and the clinical aspects of malaria. It was introduced to avoid the inclusion of the more elementary aspects of these subjects into the main course, which were not required by the more experienced students. The preliminary course occupies four days, beginning at 8 a.m. on Wednesday, 24th April.

The theoretical and laboratory studies of the main course will commence at the King Edward VII College of Medicine at 8 a.m. on Monday, 29th April, and will be completed on Saturday, 1st June.

The practical field studies will follow immediately and for this the candidates will be divided into groups, one of which will study in Malaya, one in French Indo-China, and probably another in Java. They will last approximately 21 days, during which the students will have the opportunity of becoming familiar with the routine of a malariologist and the actual application of anti-larval and other anti-malarial measures to field conditions.

Conditions of admission

The courses are intended for medical graduates already engaged, or likely to be engaged, in anti-malarial work.

The subscription for the theoretical and laboratory course will be seventy-five Straits dollars, and will be received by the Eastern Bureau of the League of Nations at Singapore.

Candidates not attending the preliminary course will be expected to possess a working knowledge of malaria and of the fundamental principles of the contributory subjects such as hæmatology, protozoology and entomology.

Any further information desired will be supplied by the Director of the Eastern Bureau, 336, River Valley Road, Singapore, to whom applications for admission to the course should be addressed. These should reach Singapore not later than 30th March, 1935, and, as only thirty candidates can be admitted, early application is desirable.

SIR BHALCHANDRA KRISHNA MEMORIAL PRIZE MEDAL

THE following letter was received by us on 19th November. We take this opportunity of pointing out once more to secretaries of medical societies the necessity for sending notices regarding medical meetings, prize essay, etc., in good time, if they really wish the general medical profession to receive the information in time to act upon it.

In this instance the notice was not issued until two months before the last day for submission of the thesis. Even then, had it been posted punctually, it might have been included in our December number.

When, however, we did receive this notice our number was made up, and it was too late to include it. Consequently only those of our readers who received information about this prize from other sources will be able to enter for it this year. Our only reason for including this notice is that the prize is to be given annually.

Dear Sir,

At a meeting of the subscribers of Sir Bhalchandra Krishna Memorial Fund held on the 11th July, 1924, the following resolution was adopted:—

'That from the funds collected to perpetuate the memory of the late Sir Bhalchandra Krishna, Kt., a Memorial Prize Medal be founded to be awarded every year on the anniversary of his death to a member of the medical profession who submits a thesis or delivers a lecture on any medical subject before a meeting of the medical profession to be held under the auspices of the Bombay Medical Union, preference to be given to one who submits any original or research work especially with reference to indigenous medicine on Western lines'.

In consonance with the above resolution, members of the profession are invited to submit a thesis or a paper by the 15th of January, 1935, to the undersigned for submission to a selection committee for making the above award.

The thesis or paper shall have to be read by the prize-man on the day of the award at a meeting of the profession to be held in accordance with the above resolution.

(Signed) Members of the Sir Bhalchandra Krishna Memorial Prize Medal Committee.

Treatment of Migraine

By MACDONALD CRITCHLEY, M.D., F.R.C.P.

(Abstracted from the *Practitioner*, Vol. CXXXIII, July 1934, p. 54)

It must be conceded that the results of treatment in migraine are not altogether satisfactory. Certainly the majority of cases, in which the attacks are neither excessively frequent nor severe, respond to a line of treatment conscientiously followed over an adequate period. On the other hand, a small proportion of cases completely fail to react to the usual therapeutic measures, which may, indeed, appear even to aggravate the symptoms. In another type attacks are of such violence and duration, and the inter-paroxysmal period is so short, that the ordinary treatments prove useless and the victim suffers an almost constant disability. Such examples of migraine major strain the resources of therapeutics.

The modern conception of migraine is that of a constitutional type of reaction to various kinds of stress. A person is either afflicted with a migrainous diathesis from an early age, or he is completely spared. He is unlikely to acquire the malady in adulthood. The migrainous constitution needs an additional stimulus, physical or psychological, before an attack is precipitated. Most often the type of stimulus is peculiar to the individual sufferer, though occasionally an attack may be produced in one person by more than one factor. The time will no doubt come when the physician will be able confidently to recognize the etiological factors in each case of migraine, to identify the particular stress, and to apply the approximate treatment. To-day, we can only aspire to such an ideal, realizing that even when the precipitating mechanisms are recognized they may still be immovable. The most important single factor in the production of migraine is to be found in errors of refraction. Without over-emphasizing the rôle of ocular defects in the etiology of migraine it must be laid down that the first step in treatment is to secure expert ophthalmic assistance.

Unquestionably the most useful drug in the treatment of migraine is luminal. The patient should persevere with this remedy for at least three months, and if it proves beneficial there is no reason why the medicine should not be continued for two or three years. Luminal is better prescribed in tablet form rather than as the soluble sodium salt. The dosage may be varied to suit the patient. One grain at night may be adequate, or gr. $\frac{1}{2}$ twice daily. In more obstinate cases, gr. i may be taken night and morning. Sleepiness and dullness do not persist with gr. i doses except in the very uncommon cases of luminal sensitivity. Grimes has suggested a combination of luminal with alkalis. He prescribes 10 grams of sodium bicarbonate in a pint of water, two hours after meals, and a $\frac{1}{2}$ grain of luminal on retiring. According to this author, this treatment should be continued for one year, four weeks at a time with intervals of two weeks.

I am inclined to regard thyroid as the next most useful drug in the treatment of migraine. The dosage should be small, as for example gr. 1/10 t.d.s. of the thyroid sicc. (1932). Nitroglycerine, an old-fashioned remedy, may be taken in the form of the chocolate-coated tablets of gr. 1/150—1/200 twice daily. It also occurs combined with strychnine and gelsemium in Gowers' well-known mixture:—

Tincturæ nucis vomicæ	mx
Tincturæ gelsemii	mx
Liquoris trinitrini	mi
Acidi phosphorici diluti	mx
Aquam chloroformi ad	ss
		t.d.s.	

The modern and more potent luminal has tended to thrust into the background the use of nitroglycerine. These three measures (luminal, thyroid and Gowers' mixture) may be employed in all cases of migraine, whatever the etiological type. There are other therapeutic possibilities in certain well-defined types of migraine of obvious nature. In cases of 'biliary' migraine, T. C. Hunt has advocated the use of bile salts. These may be prescribed as decholin (Riedel) in the dosage of one to six tablets daily. Another method is to give sodium glycocholate, in gr. 2—20 capsules. Full doses are the most efficacious, but occasionally are precluded by nausea and diarrhoea.

Cases of 'menstrual' migraine are often relieved by the regular employment of ovarian or placental extracts. A. P. Thompson suggests an injection of theelin (50 rat-units or 1 c.cm.) three times during the week prior to the period. If the headache bears no regular time-relationship with menstruation, 50 units may be injected two or three times each week. Blakie and Hossack advocate emmenin complex in one-half drachm doses twice daily for three weeks after each menstrual period. The dosage may be increased if necessary to 3i thrice daily. Our own experience with this drug has been

varied; some cases have appeared considerably improved, while others, clinically very alike, have failed to respond.

When migraine is of allergic origin, best results are obtained by the rigid exclusion of the responsible article of diet. Treatment with intravenous injection of a 5 per cent solution of peptone twice weekly, if less efficacious, merits a trial. The initial dose is 0.25 c.cm., and this is increased by 0.25 c.cm. until a maximum of 1.25 c.cm. is reached. Peptone, given by the mouth, is apparently disappointing. Some cases of migraine seem to be associated with attacks of rheumatic fibrositis, especially in the muscles of the neck and shoulders. Here relief can be obtained by the regular use of small doses of aspirin, by deep massage and radiant heat to the cervical region, and the eradication of focal sepsis. Recently, success has been claimed with chondroitin-sulphuric acid, given in capsules or as a powder. The dose is 1 gram thrice daily, or 3 grams at night.

From time to time cases of migraine resistant to all forms of medical treatment occur. To relieve such victims of their perpetual misery, help may be sought from the surgeon. Removal of the cervical and upper thoracic ganglia has been carried out in a few cases with apparent relief to the migraine. In strictly unilateral cases, in which the headache is always on the same side, Dickerson's operation of ligating the middle meningeal artery on the affected side may be borne in mind. It is difficult to be sure whether the ligation or the mere trephining is the more important factor in this form of treatment.

Treatment of a threatening attack.—Migrainous patients are frequently aroused early in the mornings by a commencing attack. Other persons, however, suffer their paroxysms in the day-time and are given abundant warning of an oncoming attack. It is possible that prompt treatment may be successful in cutting short what would otherwise be a prolonged and severe bout of migraine. A full dose of glucose or of cane sugar may be efficacious—particularly in those cases apparently brought on by hunger. An effervescent saline aperient draught is sometimes successful. Probably the best policy is for the patient promptly to give up work and to lie down, with the object of securing sleep. Reading and smoking should be forbidden, but two or three tablets of aspirin, or preferably an aspirin-phenacetin-caffeine compound, may be given with a cup of tea, coffee or maté. Another useful device is for the patient to take an extra tablet of luminal as soon as he notices the symptoms of an impending attack.

Treatment of the attack.—The victim will not need to be told to go to bed and to keep completely quiet. In the less severe paroxysms treatment will undoubtedly relieve and probably curtail the symptoms. With the more intense attacks, particularly those ordinarily lasting many hours and associated with severe vomiting, treatment is probably without avail. Morphine should, of course, be withheld. The stronger synthetic analgesics are well worth a trial, particularly when combined with a barbiturate. The following may be prescribed: one to two tablets of either veyanin (Goedecke) (codeine-aspirin-phenacetin); combral (Bayer) (pyramidon-trichlorethylurethane); veramon (Schering) (pyramidon-veronal); or dialacetin (phenacetin-diallyl-barbituric acid). Bromides are often employed, but with disappointing results. In the great majority of cases, the paroxysm does not cease with vomiting; indeed, vomiting may be obstinately present for two or three days. When nursing facilities permit, glucose enemas may be tried. T. C. Hunt has recently drawn attention to the value of adrenaline. Ten minims of a 1/1000 solution may be injected, and in severer cases 15 or 20 minims administered very slowly. Dejean has had success with injections of acetylcholine, 0.1 gram, during an attack. In the so-called 'sympatheticotonic' cases, with evidences of vasoconstriction, ergotamine tartarate (gynergen) may

be tried. This is administered either hypodermically in doses of 0.5 c.cm (7½ minims) or by mouth in tablet form.

The Present Position of the Treatment of Varicose Veins

By DAVID H. PATEY, M.S., F.R.C.S.

(From the *Practitioner*, Vol. CXXXII, June 1934, p. 695)

THE introduction a few years ago of injection treatment completely altered, almost in a night, the whole treatment of varicose veins. Operations for varicose veins disappeared from the operating lists, and the knife was banished to make room for the needle. There is now available, it was argued, a simple, safe, and sure method of treatment for all cases of varicose veins, and one moreover that can be carried out without the expense and inconvenience of confinement to bed. So great became the demand for the new treatment that many hospitals had to set up special clinics to cope with the crowds of patients, and in addition practitioners everywhere were called upon to treat large numbers of patients. Recently, however, signs have begun to appear that everything is not well with the injection treatment of varicose veins. Articles have appeared in the medical press of many countries complaining of the high incidence of recurrence after injection treatment; other papers have dwelt on the importance of prolonged after-care, and operative procedures of various types have begun to creep back. The time therefore is ripe to recast our ideas on the treatment of varicose veins. This article, based on the work of the varicose vein clinic of the Middlesex Hospital during the past four years, reviews my conclusions on the position which operation, injections, and other measures should occupy in the treatment of varicose veins to-day.

In the first place, all cases of varicose veins are not alike, and what may be suitable treatment for one case may not necessarily be so for another. The following is a simple clinical grouping of varicose vein cases together with the treatment advised for each group:—

(1) *Varicose veins filling by single, readily recognizable, and easily controlled venous trunks.*—The classical example of this is the varicose condition of the internal saphenous venous system in which there is a dilated incompetent main internal saphenous vein in the thigh, and varicosities of different sizes and degrees of complexity in the leg, all of which after emptying are controlled by pressure on the main saphenous trunk in the thigh. Before the days of injection treatment, this type of case was treated by Trendelenburg's operation, which consisted in excision of the extreme upper part of the saphenous trunk. Although this operation often gave very good results, it sometimes failed owing to the presence and subsequent development of perforating communicating veins lower down. On the other hand, injection treatment alone is not usually satisfactory owing to the difficulty of obliterating the main saphenous trunk, and the frequency of its recanalization. In these cases the most successful results can be obtained by a combination of excision and injections. Probably it is best to excise the whole of the main vein in the thigh from the saphenous opening to the inner side of the knee, and this can readily be done subcutaneously with Babcock's probes. This operation, however, requires a general anaesthetic and a stay in bed, and in order to avoid this we have contented ourselves in most cases with excising about four inches of the vein from the middle of the thigh through a vertical incision under local anaesthesia, the patient subsequently being allowed to return home. This more limited operation is performed in the operating theatre with all aseptic precautions and particular attention is paid to hæmostasis, the cut ends of the main vein being tied with two, or even three, separate ligatures. With these precautions there has

not been any anxiety about treating these cases as out-patients. At the time of the operation an injection is given into the lower end of the exposed vein. The solution used has been quinine and urethane of half the usual strength (i.e., quinine bihydrochloride approximately 5 per cent instead of the usual 10 per cent), and we have injected up to 8 c.cm., depending on the extent of the varicosities, the usual dose being 5 to 6 c.cm. At the end of the operation the leg is bandaged from the instep to above the incision with elastic adherent strapping. The patient is instructed to take things quietly for the first 48 hours, and the strapping is left undisturbed for ten days.

The results in suitably chosen cases of this combined excision and injection treatment have proved very satisfactory, and in many cases the procedure described is sufficient to obliterate the whole varicose area. If a few varicose veins still remain, they usually respond readily to one or two further injections, since the main regurgitant stream has been cut off.

We also endeavour to apply this combined treatment in other similar types of varicosity besides the classical internal saphenous, whenever it can be demonstrated that there is a varicose system fed predominantly by one venous trunk controllable by pressure.

(2) *Early varicose veins.*—A type of case frequently seen is that of a young woman or girl who has noticed a few small varicose veins and comes because of their bad cosmetic effect, rather than because they are causing any trouble. Cases of this type are the most satisfactory for pure injection treatment; the veins usually respond readily, the treatment is not prolonged, and experience proves that the late results are good. A word of caution, however, is necessary about the treatment of these cases: sometimes in anxiety about the beauty of her legs, the patient comes with veins so small that their injection would be very difficult. It is best, therefore, owing to the disastrous effects following leakage of the solutions into the subcutaneous tissues, not to be too ambitious in these cases, and to treat those veins only which can quite certainly be safely injected.

(3) *Extensive varicose veins filling through numerous venous trunks, difficult to recognize, and impossible to control by proximal pressure.*—This is a very difficult type of case to deal with. Treatment by operation alone is unsatisfactory, since it is practically impossible to secure all the communicating venous trunks through which the varicose veins fill. Injections in many cases undoubtedly give considerable symptomatic relief and cosmetic improvement, but the treatment has definite disadvantages and limitations. For in these extensive cases it is a long and tedious business for both patient and practitioner, often extending over many months, and at the end recurrence owing to recanalization of obliterated veins is not unlikely. Each case has to be judged on its merits, and it is probably best to explain fully to the patient the possibilities and the difficulties, and to weigh carefully other factors, such as the age and temperament of the patient, before deciding whether active treatment by injections or palliative treatment by supporting bandages is best suited to the particular case.

(4) *Very large varicose veins.*—Very large varicose veins are difficult to obliterate by injections; large doses are usually required, and, if successful, the resultant local reaction is likely to be severe. For this reason, very large varicose veins are probably best treated by excision or a combination of ligature and injections.

(5) *Dilated skin venules.*—In some cases the patient is chiefly concerned about collections of small dilated skin venules rather than subcutaneous varicose veins. The treatment of these skin venules is not very satisfactory, as they do not as a rule lend themselves to direct injections. If there is an obviously communicating subcutaneous varicose vein, the injection

of this sometimes does good. Otherwise, the possibility of x-ray or radium treatment as for angiomas should be considered.

(6) *Varicose veins associated with ulcers.*—The relation of varicose ulcer to varicose veins is not always clear. Thus, on the one hand, very well-marked cases of varicose veins without the slightest trace of skin bluish are common, and, on the other hand, varicose ulcers without any trace of varicose veins are frequently seen. But if varicose veins are present in association with ulcers, it is as well to give the patient the benefit of the doubt and, in addition to treating the varicose ulcer, to treat the veins actively by the means best suited to the particular case. Unfortunately, it is impossible absolutely to guarantee that the treatment of the varicose veins will prevent the recurrence of the ulcer.

(7) *Varicose veins associated with other leg troubles.*—Finally, patients with varicose veins not infrequently suffer from symptoms due to other troubles, such as foot strain. It is, of course, important to recognize this, as the proper treatment in these cases is that of the condition causing the symptoms, the veins often not requiring active treatment.

Conclusion.—Many points in the aetiology of varicose veins are still obscure, and until these are cleared up treatment cannot be entirely rational and satisfactory. At present it is necessary to recognize that cases of varicose veins fall into different clinical types demanding different types of treatment. But contrary to what is sometimes thought, surgical methods still occupy an important place in the treatment of varicose veins, and the best results are obtainable in cases in which surgical and injection methods can be combined.

Typhus Fevers in the Tropics

By SIR JOHN MEGAW, K.C.I.E.

(Abstracted from the *British Medical Journal*, 11th August, 1934, p. 244)

THE title of the present discussion is 'Tropical Typhus', but this name is obviously inappropriate, as the fevers with which we are dealing occur just as frequently in cold countries as in hot. A more suitable name is 'Typhus Fevers in the Tropics', and although some experts are sure to object, I will adopt this until something better is suggested.

TYPHUS AS AN EPIDEMIC DISEASE

'Every schoolboy knows' that the name 'typhus fever' was originally applied to typhoid and relapsing fever as well as to typhus. In 1837 Still and Gerhard showed that typhoid fever was a distinct disease, and in 1843 Henderson differentiated relapsing fever. In 1862 Murchison emphasized the contagious nature of typhus fever. Nicolle and Conseil, in 1909, proved that the disease could be conveyed by lice. Between 1906 and 1910 Ricketts and Wilder suggested that the bodies now known as Rickettsia bodies were the causal organisms of typhus fever and Rocky Mountain spotted fever. In 1910 Wilson of Belfast discovered that the sera of typhus patients agglutinated organisms of the *coli* group which had been isolated from cases of the disease. He was careful to point out that he did not regard this agglutination response as indicating that the organisms caused typhus fever. Weil and Felix in 1916 described the reaction which is now known by their name; they used an organism called 'proteus X 19'.

Until recently typhus exanthematicus was regarded as being essentially different from the other fevers which resembled it so closely in their clinical features; the reason being that these fevers were in sharp contrast with typhus in not being epidemic diseases

associated with crowding, poverty, filth, and lice, and in not being directly communicable from man to man. Accordingly, even the spotted fever of the Rocky Mountains, which closely resembles typhus, was regarded by nearly all observers as belonging to a different disease group, until Wolbach, in his masterly monographs on the subject in 1916 to 1919, showed the essential similarity in the pathology of these two fevers. Sambon, however, had previously insisted that they were really the same as typhus fever.

So long ago as 1897 Brill of New York had discussed the relation between the disease which now goes by his name and typhus fever; he concluded that the epidemiological differences were so great as to make it impossible to place the two fevers in the same group, but in 1912 Brill's disease came to be regarded as an inter-epidemic form of typhus, because its virus was found to protect animals against typhus.

At this date the position was that typhus fever was regarded as a unitary disease, while the Rocky Mountain and Japanese fevers were considered as belonging to a different category; they were known to be communicated from rodents to man by ticks and mites respectively.

INSECT VECTORS IN OTHER DISEASES RESEMBLING TYPHUS

A brief reference must be made to some fevers, the aetiology of which was not known at first, but which are now recognized as belonging to the typhus disease group. In 1910 Smithson in Queensland described a fever resembling Brill's disease; he suspected that the vector was some insect living in sugar canes. The same year Connor and Bruch described a similar disease in Tunis, and called it 'fièvre boutonneuse'. In 1911 McNaught gave an account of an anomalous form of paratyphoid occurring in South Africa. In his report he makes a significant reference to a suggestion by Colonel Maher that the fever might be connected with ticks, since he found that some of the patients had been bitten by ticks prior to the onset. McKechnie, in 1913, wrote a very interesting report, unfortunately never published, of a fever prevalent in one locality in the Kumaon region of the lower Himalayas. He called this fever typhus, and suggested fleas, bugs, and mosquitoes as possible vectors. Two years later, in 1915, Schüffner described a pseudo-typhus fever in Sumatra, and suspected a tick or mite of being the vector. The name given by Schüffner would probably be more correctly translated into English as pseudo-typhoid, as I understand he was thinking of typhus abdominalis rather than typhus exanthematicus.

NON-EPIDEMIC TYPHUS IN INDIA

My own experience of a non-epidemic typhus fever was thrust upon me rather than sought. In June 1916, while in the near neighbourhood of the place where McKechnie had already reported his cases of typhus, I found a tick on my neck in circumstances which indicated that it must have attached itself about twelve hours earlier. Some twenty days later, after returning to Lucknow, I began to suffer from fever with a step-like rise in temperature; within four days an eruption appeared, which recalled to my mind the descriptions I had read of the Rocky Mountain fever. At that time no human disease was known to be conveyed by a tick in India, so I had light-heartedly thrown away a very interesting specimen which, within a few days, assumed considerable importance as being the only likely vector of my attack of fever.

I wrote an account of my case in the *Indian Medical Gazette* of January 1917, in which I suggested that the tick must have been either *Rhipicephalus sanguineus* or *Hyalomma aegyptium*. This, I think, was the first case in which definite evidence was produced

of a tick being the vector of a typhus-like fever outside the Rocky Mountain fever zone. I also suggested that McKeechnie's Kumaon fever and the fevers described by Conor, McNaught, and others should be classed with the spotted fever of Idaho and Brill's disease as a sub-group of typhus fever, differing from that fever in being conveyed by ticks or fleas, in being place diseases, and in having no connection with lice, famine, dirt, or overcrowding. I fell into one serious error in regarding the low virulence of these diseases as being an important feature in differentiating them from classical typhus, but apart from this I have nothing to retract from what I wrote nearly eighteen years ago.

Several readers of my note, including Major-General Sprawson and Colonel Chapman, sent me accounts of similar cases which they had observed in various places in India. On the strength of these reports and after further study of the subject, I felt justified in suggesting in a paper published in the *Indian Medical Gazette* of October 1921 that a fever conveyed to man from an animal of the wilds by a tick was widely distributed in India and probably in other parts of the world; that this could not be clearly distinguished from the Rocky Mountain fever; and that it, with the other sporadic typhus-like diseases, should be classified as members of the typhus fever group. Accordingly, I suggested the classification 'louse typhus', 'tick typhus', and 'mite typhus'. In later papers I produced evidence of the frequent occurrence of tick typhus in various parts of India as well as in other countries, and added to my previously proposed classification another heading—namely, 'typhus of unknown vector'.

FLETCHER'S WORK IN THE FEDERATED MALAY STATES

Apart from work in the Rocky Mountain, Japanese, and Indian areas, there was little evidence of interest in the sporadic typhus fevers until 1926, when Dr. William Fletcher described a number of cases of 'tropical typhus' in the Federated Malay States. Dr. Fletcher was struck with the resemblance between his cases and those described by me in India, but he found no evidence of tick bite, and the agglutination response to *proteus* X organisms was quite different in his cases from that observed in India. In the Indian tick typhus the Weil-Felix reaction was usually negative, or positive only in such dilutions as 1 in 80 or 1 in 100 to *proteus* X 19, whereas Fletcher found two sharply contrasted groups of cases, one of which gave a strongly positive reaction to *proteus* X 19 and was negative to the Kingsbury strain of *proteus*, while the other reacted to the Kingsbury strain of *proteus* X but was negative to *proteus* X 19. At first the differences between the two forms of tropical typhus and tick typhus were rather puzzling, but recent work indicates that there really are three distinct types of sporadic typhus—namely, tick typhus, mite typhus, and flea typhus—and that each of these shows a distinct characteristic agglutination response towards *proteus* X organisms.

Apart altogether from its great intrinsic value, Dr. Fletcher's report was very important in attracting the attention of the medical world to these sporadic typhus fevers. Within the past few years a vast number of observations have been published showing that the fevers of the typhus group are very widespread in their distribution and of considerable practical importance.

It was not until 1930 that Durand, Conseil, and Brumpt demonstrated the conveyance of 'fièvre boutonneuse' by a tick, *Rhipicephalus sanguineus*, which was one of the two suspected by me in 1916. Now we know also that the form of sporadic typhus which conforms to Brill's description is conveyed from rats to man by fleas, so that to my previous provisional classification there must now be added another sub-group—'flea typhus'.

NEED FOR UNIFORM NOMENCLATURE

A few words must be said on the subject of the classification of the typhus fevers. Dr. E. W. Goodall objected to Dr. Fletcher's use of the name 'tropical typhus', on the ground that all the typhus fevers ought to be called typhus pure and simple, irrespective of the vectors concerned and any other differences that exist between them. While I object to the name 'tropical typhus', I object much more strongly to the position adopted by Dr. Goodall, for although the sporadic fevers are very similar to louse typhus in their clinical and pathological features, they are poles asunder in their epidemiology and in the measures that are called for in their practical management. If the name 'typhus' were applied to all fevers of the group without further qualification a very misleading suggestion would be conveyed.

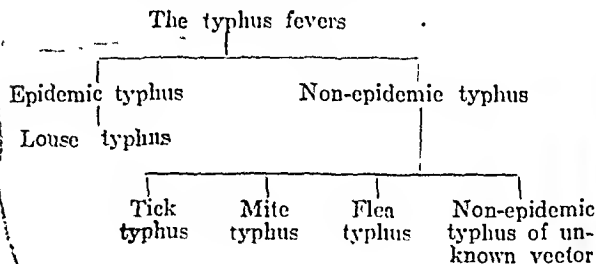

Disease nomenclature is intended to be helpful to the medical man, and should be as simple as possible, but if we attempt to secure simplicity by lumping together things that are essentially different the only result will be confusion. The classification of the typhus fevers is a matter of real importance, and I take this opportunity of appealing once more for the adoption of a uniform and rational nomenclature. The need for this step is evident when we consider that more than a dozen different names were given to the sporadic typhus fevers in a single recent issue of the *Tropical Diseases Bulletin*. Here is an incomplete list of twenty-seven names which have been used during the past few years for these fevers: spotted fever of the Rocky Mountains, fièvre boutonnière, fièvre exanthématique, fièvre escharo nodularis, eruptive fever, macular fever, Marseilles fever, jungle typhus, spotted fever of the Eastern type, tick-bite fever, tick fever, Brill's disease, tropical typhus, endemic typhus, sporadic typhus, shop typhus, ship typhus, murine typhus, tabardillo, Mexican typhus, flea typhus, Manchurian typhus, Japanese river fever, tsutsugamushi, pseudo-typhoid of Deli, Mossmann fever, and mite typhus. This is an appalling list, the only redeeming feature of which is the growing tendency to use the name typhus. Place names are obviously unsuitable; they suggest that the disease is restricted to one locality—for example, I could not have described Indian tick typhus as Rocky Mountain fever. Names like 'spotted' or 'macular' are also unsatisfactory; there are so many fevers in which spots or macules appear that the name becomes meaningless.

My provisional suggestion that the word typhus qualified by the name of the vector should be employed was open to criticism, because the vector was often unknown or doubtful. This perfectly sound objection can only be met by a frank confession of ignorance when the actual vector is unknown or doubtful, and accordingly employing the non-committal general term 'non-epidemic typhus' to indicate those fevers which are not conveyed from man to man by lice as contrasted with 'epidemic typhus', which has a human reservoir of infection. The term 'endemic' would be neater and better than 'non-epidemic', but it has already been earmarked as a name for flea typhus, and therefore could not be used without risk of confusion.

SUGGESTED CLASSIFICATION

Evidence is now accumulating to show that the specific agglutination response of each of the non-epidemic typhus fevers is associated with the vector concerned, so that we may soon be able to classify the fevers according to the vector, even when there is no direct evidence as to which arthropod is responsible in any given case. With the rapid accumulation of more knowledge of the geographical distribution of the fevers, difficulty in assigning each case to the appropriate vector should soon disappear. Until

something better is proposed I therefore suggest the following modification of my original classification.

This classification is not ideal, since, apart from the occasional difficulty of determining which vector is concerned, we are not yet able definitely to state that there are four distinct types of virus. In louse, tick, and mite typhus the evidence is already fairly strong that each virus is different from the others; at any rate there is no case on record of direct communication of tick or mite typhus from one person to another, and, after all, the manner of conveyance of the diseases is by far the most important practical matter from the physician's point of view. Flea typhus is so closely related to louse typhus in its immunological and serological aspects that careful research will be needed to determine whether or not the virus of louse typhus can ever be transmitted by fleas. If this virus be transmissible by fleas it must be greatly attenuated in the process, since flea typhus is the one type which has never been found to be severe. There is no evidence that any of the non-epidemic typhus fevers has ever started in a louse-borne epidemic, so that although there may be some mental reservations regarding the relation of the fevers, practising physicians can safely base their action on the hypothesis that epidemic and non-epidemic typhus fevers are essentially distinct from each other.

DIFFERENTIAL DIAGNOSIS

I have already referred to the error into which I fell eighteen years ago with regard to virulence; the truth is that tick typhus and mite typhus may be very mild or very severe. The same applies to a lesser extent to louse typhus, which is sometimes quite mild. Flea typhus alone has a consistent record of mildness so far, although severe or even fatal cases have been recorded. Another point which is sometimes relied on for differential diagnosis between the various forms of non-epidemic typhus is the presence or absence of local necrosis at the site of infection associated with lymphangitis. This feature is sometimes present and sometimes absent, both in tick typhus and mite typhus; it cannot, therefore, be relied on as a point of distinction between the two fevers. Agglutination and animal inoculation tests are not always conclusive, so that when there is no positive evidence regarding the vector, difficulty may arise at times in individual cases in distinguishing between the three types of non-epidemic typhus.

On the other hand, there will seldom be any difficulty in deciding whether any given fever belongs to the epidemic or non-epidemic group if all the circumstances of each case or outbreak are investigated. After all, the chief concern of the medical man is to decide whether he is dealing with a disease which calls for extremely careful precautions to prevent spread to other human beings or with a disease not communicable from man to man.

Serological tests against two or more varieties of *proteus* X organisms will often be of great help in diagnosis, and knowledge of the local conditions will usually make it possible to be reasonably certain of the particular vector which is concerned.

We are now at an interesting stage of the investigation, and with so many intelligent observers at

work throughout the world we seem to be rapidly approaching the time when the non-epidemic typhus fevers will be completely rescued from the small and rapidly diminishing group of fevers of unknown or doubtful aetiology. The most astonishing feature of the non-epidemic typhus fevers is that they escaped recognition so long in many parts of the world, in spite of their striking and characteristic features.

The Pain of Herpes Zoster Treated with Pituitrin

By FRANCIS H. GILLET, M.B. (Camb.)

(Abstracted from the *Lancet*, 11th August, 1934, p. 307)

DRAMATIC results with the injection of pituitrin for the treatment of herpes zoster have been reported in the American and continental medical press during the last few years, and considering the remarkable relief which sometimes is given to the patient by these injections, it is surprising that the treatment receives so little attention.

Sidlick in 1930 described four cases from a series of 54 patients suffering from herpes zoster treated with pituitrin. These four suffered agonizing pain and the treatment was most efficient. Niles in 1932 also described a series of 16 cases treated with pituitrin, and considers that the most brilliant results were obtained in the very early cases and that the course of the disease was shortened by about two and a half days. He found that the severe pain was usually rapidly relieved. The writer treated a number of cases of which he reports three in detail, giving 1 c.cm. of pituitrin intramuscularly; it usually caused complete disappearance of the pain almost immediately. He draws the following conclusions from comparison of his experience to that of others:—

I have found that the injection of pituitrin is an uncertain and by no means an infallible treatment. It appears to act most dramatically when the pain is most intense. I can at present offer no explanation of why this should be so, but the treatment is a valuable asset to the practitioner in his attempt to relieve a patient from the pain accompanying herpes zoster.

The Value of Tuberculin Tests

By HALLIDAY SUTHERLAND, M.D.

(From the *Medical Press and Circular*, 15th August, 1934, Vol. CLXXXIX, p. 155)

'In its beginning the malady is easy to cure, but difficult to detect; but in course of time, when neither detected nor treated, it becomes easy to detect but difficult to cure'. So Machiavelli wrote about pulmonary tuberculosis over 400 years ago; but now, by means of the tuberculin tests, the earliest suspicion of tuberculosis may be confirmed or negated with certitude. There is a heavy responsibility on anyone who neglects to use this means of diagnosis.

For the patient the difference between early and delayed diagnosis may mean life or death. If diagnosis be delayed until tubercle bacilli appear in the sputum, the patient has probably infected the members of his family. To delay diagnosis until the patient is seriously ill means that he must abandon work and undergo sanatorium treatment, which is costly.

In the early afebrile stage the patient could have been immunized ten thousandfold with tuberculin at a fraction of the cost of sanatorium treatment, and without the necessity for giving up work.

At the Westmoreland Sanatorium I once awaited the arrival of a patient certified by his doctor to be an early case. A cab came up the drive and inside the cab was the patient—dead. That is an extreme case. Yet in many sanatorium cases the disease could have been diagnosed months, or even years, earlier if the general practitioner had looked for early symptoms and

used the tuberculin tests. Patients will often hide the truth from their doctor, but some of the early symptoms are always present: a dry, explosive cough called 'the stomach cough', a little phlegm in the morning, 'colds that fly to the chest', loss of appetite and weight, dyspepsia, and pain in the chest, with or without signs of dry pleurisy.

These are the early symptoms, but no one who relies solely on physical, radiological and sputum examination is capable of making an early diagnosis with any certitude. The physical signs of early pulmonary tuberculosis are not diagnostic. They may occur in other diseases of the lung, or may be absent. A tuberculous nodule must attain a size of four cubic millimetres before its shadow is thrown on to a radiogram. Increased apical striation is suspicious, but not diagnostic. Nodules, mottling, and excavation are radiographic signs of advanced disease. The presence of tubercle bacilli in the sputum is not a sign of early tubercle, nor does their absence exclude tuberculosis. With early signs and symptoms it is impossible to make a firm diagnosis one way or the other, unless tuberculin tests are used. In cases where no tubercle bacilli are detected in the sputum, but whose symptoms, physical signs or radiograms suggest the possibility of tubercle, I begin with the cutaneous test.

THE CUTANEOUS TEST

The front of the forearm below the elbow is cleansed with ether, a drop of old tuberculin is placed on the skin, and the cuticle under the drop is tattooed with a hollow needle. In children the back of the shoulder is selected. The needle merely pricks the cuticle and there should be no bleeding. No dressing is required.

A positive action may appear within six to forty-eight hours: a raised, circular, reddened indurated area of skin, slightly tender to the touch. The extent of induration varies with the severity of the reaction, reaches its height within three or four days, and then begins to disappear. A negative reaction may show transient redness within forty-eight hours, but no induration.

Some prefer the intracutaneous test, in which the reaction is obtained by injecting 0.1 c.c. of a 1 in 1,000 solution of old tuberculin under the cuticle, but not under the skin. The reaction is more painful than the cutaneous test, and is more likely to provoke a general febrile reaction, or even a focal reaction at the site of the disease. The intracutaneous test gives a higher percentage of positive reactions than the cutaneous test; but that is of little advantage, because the main value of both tests is when they give no reaction, and thus enable us to exclude a diagnosis of tuberculosis. In the case of nervous children the percutaneous test is very useful. An ointment of 50 per cent tuberculin in lanolin is rubbed with a finger stall into the skin. A piece the size of a pea is sufficient. In one or two days a papular eruption on an erythematous base may appear.

INTERPRETATION

A negative skin test, except in patients dying of tubercle, shows that the body has been, and is, free of tuberculous infection. Most healthy adults have been infected at one time or another with tubercle bacilli, and so in the great majority of cases the test is positive and of little value in diagnosis, because the skin tests cannot distinguish between latent and active disease. At the age of twenty-six I had a negative cutaneous test before going as resident physician to the Royal Victoria Hospital for Consumption. Six months later I was a 'positive'. In the interval I had been infected, and remain infected, although the disease has never developed. A positive skin test has more significance in children, especially in children under five; but even then it is not diagnostic, because of clinically non-tuberculous children, 20 per cent react to the cutaneous test and 40 per cent to the intracutaneous test:

All the skin tests are qualitative. They reveal the existence of tuberculous infection, without giving any indication as to whether infection is latent or active. Various attempts have been made to make these tests quantitative, in order to distinguish between active and latent infection, but without success.

THE SUBCUTANEOUS TEST

When the cutaneous test is positive I proceed to the subcutaneous test with a view to discovering whether the infection is latent or active. In the subcutaneous test we look for a rise of temperature. Consequently the test can only be done in afebrile cases. If there is fever, this must first be subdued by rest in bed. The patient charts the temperature at 8 a.m., 4 p.m., and 8 p.m. There are two degrees of reaction: a weak reaction—a rise of temperature of from $\frac{1}{2}$ to 1°F. above the mean temperature; a strong reaction—a rise of over 1°F. A weak reaction is not diagnostic unless confirmed by a strong reaction to the same dose repeated, or by a strong reaction to a larger dose.

I inject the following doses of tuberculin albumen free: 0.0001 c.c., 0.0002 c.c., 0.001 c.c., 0.005 c.c. and 0.01 c.c., with an interval of at least two days between each injection. For children under fifteen with slight signs and symptoms, the first dose is 0.00001 c.c., and for children and adults with signs of active disease in the lungs the initial dose is one ten-millionth of a c.c. Here the dose is apparently infinitesimal; but in a girl of eight with tuberculous glands in the neck I have seen a rise of temperature of 4°F. after an injection of one millionth c.c. Injections are made over the lower ribs below the scapula, where the skin is least sensitive.

The tuberculin test has a double value. A tuberculous individual reacts to an amount which has no effect upon a healthy person. Koch regarded 0.025 c.c. as the amount which usually produced symptoms in healthy adults. Therefore the value of a reaction as indicative of tubercle is in inverse proportion to the amount injected. A reaction to a small amount is of greater diagnostic value than a reaction to a larger amount. Conversely, the absence of a reaction to a large amount of tuberculin is of more value in excluding tuberculosis than the absence of a reaction to a small amount. A tuberculous subject may give three types of reaction to tuberculin: (a) Local, at the site of injection; (b) general, a rise of temperature; (c) focal, and exacerbation of signs in the tuberculous lesion. In the subcutaneous test we seek to provoke a rise of temperature only. A febrile reaction to any dose of old tuberculin up to 0.001 c.c. is definite evidence of active tuberculosis, whereas no reaction to 0.01 c.c. excludes active disease, and in all probability even latent infection. This is not a mechanical method of diagnosis, because around reactions to 0.005 c.c. there is a no-man's-land, where every other factor in the case must be weighed equally in the balance. A reaction to 0.01 c.c. cannot be accepted as evidence of active tuberculosis, because many individuals clinically non-tuberculous react to this amount.

It has been said that the subcutaneous test is dangerous. So also are injections of morphia and strychnine if too large doses be given. All tests may be dangerous in the wrong hands, but the subcutaneous test is no more dangerous than the intracutaneous test. In both tuberculin is injected into the body. By the subcutaneous route it is more rapidly absorbed than by the intracutaneous method. Yet it is possible to provoke a febrile reaction by the von Pirquet test or even by the Moro test, where tuberculin is absorbed through the skin. Moreover, the subcutaneous test avoids one danger of the intracutaneous test, ulceration of the skin over the indurated area.

Of all tuberculin tests I have found the subcutaneous the most delicate and useful in clinical diagnosis.

Psychoses in Cases of Malaria following Exhibition of Atebrin

By A. NEAVE KINGSBURY, M.D. (Lond.), D.P.H.
D.T.M. & H.

(From the *Lancet*, Vol. II, 3rd November, 1934, p. 979)

THAT certain toxic symptoms occasionally follow the exhibition of atebrin in cases of malaria is now well established. Headache, epigastric pain of a colicky nature, and yellowing of the skin and sclerae, quite unrelated to jaundice, are usually encountered in a small percentage of treated cases. Another phenomenon, first reported by Dr. O. F. Conoley in a paper (unpublished) read by him in 1933, has been described as 'cerebral excitation'. This interesting complication was brought into prominence during a local discussion on the toxic effects associated with the use of atebrin, admirably opened by Green in December 1933. During that discussion five cases of 'cerebral excitation' and also one case of intense mental depression and one of delusional insanity were described.

Early this year Dr. D. M. McSwan presented a short paper (unpublished) that included brief notes of three cases of 'cerebral excitation' and two cases of mental confusion. One of the latter cases was transferred to a mental hospital; the second was discharged, but about three weeks later was also admitted for mental treatment. Since my return from furlough, early this year, some of my colleagues have kindly communicated to me particulars of further cases that had developed suggestive symptoms.

SUMMARY

1. Seven cases of psychosis following the exhibition of atebrin to cases of malaria have been collected. Five previously unpublished cases have been cited and five more cases are recorded. These occurred among several thousand cases of malaria treated with atebrin.

2. Psychoses may occur in either sex and have occurred in five nationalities. Symptoms have developed in benign and subtertian cases and in cases with mixed infections. The complication has been noted after a minimum of 6 tablets (1 tablet t.d.s., i.e., 0.3 g. daily), a maximum of 21 tablets and an average of 13 tablets. The minimum interval between the commencement of treatment and the onset of symptoms was 1½ days, the maximum 12 days (5 days after the completion of the course) and the average 5½ days.

3. The duration of symptoms in eight mild cases varied from ½ to 7 days, with an average of 1½ days. Four more severe cases were referred to mental hospitals.

4. One mild and one severe case had histories of previous mental breakdown. Another severe case had a bad family history.

5. Two factors may be involved in the causation. The action of atebrin *vis-à-vis* the malarial parasite may result in an intense liberation of 'toxins': on the other hand, atebrin (in lethal dosage) is known to have a toxic action on the central nervous system.

6. Although the plasmodicidal effect of atebrin in a daily dosage of 0.2 g. is less favourable than that obtained with a larger intake, it is suggested that the risk of the development of psychoses would be minimized by caution in the selection of the daily dose.

The Treatment of Chronic Gravitational Ulcers of the Legs

By A. DICKSON WRIGHT, M.S., F.R.C.S.

(From the *Medical Press and Circular*,
Vol. CLXXXIX, 5th September, 1934, p. 205)

ULCERS of the leg are an ever-present problem in medical practice. Inability to handle these cases on our part has driven probably half the sufferers to

quacks and patent medicines. These patients should properly be ours, and would be if all cases were treated systematically on a definite régime as outlined in this article. Practically all the ulcers of the lower part of the leg are the result of gravity and can be called gravitational ulcers, and they are a manifestation of decompensation of the venous circulation of the legs. There are a few exceptions to this rule; Syphilitic ulcers, secondarily implanted soft sores, ulcers serpigiosus and mycotic sores provide most of these, and in the tropics the spirochaetal ulcus tropicus is very common in certain localities. 'Splenic' ulcers occur in certain splenic diseases, 'gluttony' ulcers in the obese, and Bazin's ulcers in tuberculous young women and legs affected with infantile paralysis. These exceptional ulcers, though of numerous types, only form perhaps one per cent of cases; the other ninety-nine are due to venous imbalance from the following causes:—

1. Varicosity of superficial or deep veins, or both.
2. Obliteration of superficial or deep veins, or both, by thrombosis.
3. Incompetence of involved veins resulting from canalization of thrombosed veins.

The result is the same, whatever the cause, and results in holding up of œdema and katabolites in the leg with resulting reduction in resistance to trauma and infection.

Whatever the cause the treatment is the same, *viz.*, to balance the arterial and venous circulations, and the indication of the accomplishment of this is the abolition of œdema, and once this is obtained the ulcers, eczema and periphlebitic induration will disappear in the most remarkable manner. To simplify treatment, six grades of ulcer will be considered.

1. *The indolent abrasion* or burn over the lower part of the leg which refuses to heal, although there is no marked varicosity or œdema of the leg. Place a strip of elastoplast loosely over the abrasion and pinch together so as to narrow the ulcer, and then secure with another strip of elastoplast and change every four to seven days, and the ulcer will quickly heal (see illustration).

2. *The small ulcer*, which is located at the lower end of a long system of varicose veins, generally

Method of pulling margins of ulcer together by pinching up a fold of sticking plaster.

starting at the saphenous opening. The ulcer is clearly the result of this one group of veins, and is not a sign of a generally disordered circulation of the leg.

Inject the veins from above down, starting with 5 c.c. sodium morrhuate 5 per cent. If no effect is obtained, change to 5 c.c. lithocaine solution (30 per cent lithium salicylate and 1 per cent tutocain), and if this again fails, try simultaneous injection of equal amounts of quinine 12 per cent and urethane and lithium salicylate into the same vein. Finally, if this fails, the vein should be ligated about 6 inches below the saphenous opening and injected with lithocaine solution 2½ c.c. above and below the ligature. This latter procedure will initiate a prompt thrombosis, and the remaining veins thrombose readily by subsequent injections at four-day intervals. During the treatment the ulcer below is strapped locally as described previously. Finally, when the veins are all thrombosed the whole leg from the toes to the knee is firmly strapped with elastoplast for fourteen days, and by this procedure the ulcer, if not already healed, will quickly close and the pressure of the elastoplast will cause the venous inflammations resulting from the injections to clear up promptly, leaving the veins as firm cords unlikely to recanalize.

3. *The moderate-sized ulcer* of up to four square inches, occurring on a very oedematous leg which has, in all probability, a valvular deficiency of the deep veins as well. Such an ulcer often occurs as a result of a white leg occurring generally more than twelve years previously. It seems to take this period of time for the leg to reach the ulceration stage. One-inch strips of Zopla plaster are applied tightly across the ulcer so as to pull the edges together and then the leg should be tightly bandaged with elastoplast, laying longitudinal strips on the narrow part of the leg and finally strapping the leg over these from toes to knee. The strapping is renewed in three days' time, because it becomes loose from the reduction of oedema. A better plan, of course, is to put the patient to bed for three days with the bed sloped, and then to start strapping while still in bed with the leg shrunk. This is, of course, not practicable in hospital practice. The strapping is again renewed after four days, and further changes at seven- or fourteen-day intervals. The veins in the thigh are injected each time the bandage is changed. It is not of much value to inject the leg veins at this time, because, as a rule, the injections do not take if the elastoplast is applied over the injected veins. When the ulcer is healed then the veins in the leg are injected and *ichthopaste bandages* used to support the leg, and it is interesting that the injections seem to take under this type of bandage. The technique of applying these bandages is important. The bandages (two) are warmed in a water bath and applied smoothly from toes to knee. The direction of the bandage should be frequently changed by cutting the bandage and changing hands, the secret being to apply short lengths instead of laying the bandage continuously, as one would do with a roller bandage. The support should be finished off with a firm crepe bandage, which sticks to the underlying moist bandage and gives an excellent combination of rigid support from the gauze ichthopaste bandage and elastic support from the crepe. Such a bandage will last anything up to six months, according to the type of patient, and then should be changed for another or a good elastic stocking. The necessity of a permanent support will depend upon two things: the amount of work and standing the patient has to do and the degree of venous incompetency left after thorough injection of the superficial veins, and this will depend upon the existence of previous deep phlebitis and valvular incompetence of the deep veins.

4. *The very indurated ulcer* on a leg solid with unpittable callous oedema resulting from long-standing circulatory imbalance. These cases should receive the tightest possible bandaging, and the most amazing reductions in size can be effected, and by displacement measurement I have in one case expelled no less than eight pints of oedema from such a leg. In addition to the strapping described in type III, a piece

of sorbo sponge should be incorporated in the bandage over the site of the ulcer. The sorbo should not be in contact with the ulcer, but separated from it by the short strips of Zopla and the longitudinal strips of elastoplast.

5. *The malleolar ulcer* occurs more commonly not on the malleolus but in the sulcus which surrounds it. This type of ulcer is especially common in cases of old femoral thrombosis, and it frequently develops even when elastic stockings are worn, because the stocking supports every part of the leg but the perimalleolar depressions. To overcome this I have had special pads made (Down Bros.) to support this part of the leg. These ulcers cause much suffering and are often known as irritable ulcers, the pain frequently being most marked in the area below the ulcer rather than in the ulcer itself; the title describes not only the ulcer but the patient's frame of mind, and these cases need much humoring and coaxing. To lessen the pain, pure amorphous aspirin (not crushed tablets) or percaïn powder may be dusted on, then the ulcer edges are pulled together with thin strips of adhesive. Over the adhesive is placed a two-inch square of 'elephant' plaster (adhesive felt), and over this a one-inch square of sorbo or onazote ½ inch thick. Finally, the whole leg is bandaged from toes to knee with a firmness proportional to the oedema. Injections are carried out as before with the greatest thoroughness, and finally an ichthopaste bandage is applied, and then, to consolidate the cure, an elastic stocking with the malleolar pads. During the early stages of the treatment recourse must be made to barbiturates and aspirin or codein to get peaceful nights, or the patient will disappear.

6. *The ulcer occurring in association with extensive eczema.* In these cases one feels nervous about applying elastoplast over such tender skin. It should always be tried nevertheless, but removed in two days to see if it suits. Fifty per cent of eczematous cases are cured with elastoplast; the other fifty per cent will be cured by the alternatives of 'ceraban' or 'ichthopaste' bandages. Very thorough injection is very necessary in eczematous cases, and the application of ung. bism. et quinoline (Stewart) or crude coal tar, 1 drachm, zinc oxide, 1 drachm, lanolin and vaseline ad. 1 ounce, under alternate bandages, is of value.

7. *Extensive ulcers* of 10 square inches up to the maximum size of 140 square inches. These ulcers always occur on very oedematous legs and require very firm bandaging or rest in bed at first to reduce the swelling. The profuse discharge leads to sliding of the bandage, so it is necessary in the more extensive ulcers to prevent the possibility of the bandage cutting by elephant plaster rather than the usual longitudinal elastoplast strips. Skin grafting is of great help in these cases, securing a more rapid healing before the skin gets 'sick' of elastoplast. The grafting is done by implanting seeds of skin under the granulations, or sewing skin strips into the granulations. The grafting does not interfere with ambulatory treatment, and after their use the same bandaging method is used. Again, consolidation of healing is secured with ichthopaste and permanence of cure with thorough injection and elastic stockings, worn for ever if thought necessary in bad cases.

Contraindication to these lines of treatment is only found in cases where arteritis is also present and the angle pulses cannot be felt. The principles of treatment should not be abandoned if eczema or blistering occur under the elastoplast. This dermatitis is of three types:

1. A simple patchy eczema of a mild type, and this can be ignored as a rule and will disappear, especially with tighter application.

2. A localized area of acute dermatitis round the ulcer, as if the combination of the discharge and the bandage composition excited an acute cutaneous inflammation. This can be dealt with by bandaging the leg with gauze before applying the elastoplast or

by laying longitudinal strips of lead adhesive (ceraban) over the raw area. In many cases this dermatitis does not occur under Zopla strips.

3. Definite allergic response shows itself by intense inflammation wherever the adhesive touches and also a generalized urticaria affecting face, neck, forearms, and so on. This may make its appearance with the first bandage in a sensitive individual, but in others it may not appear until after sensitization has occurred as a result of applying many bandages. The solution lies in changing over to 'ceraban' bandage, and if this produces the same effect ichthiopaste can be used. It is most important to adhere to the main principles of treatment—namely, compression. It is this and not the composition of the bandage which cures the ulcers.

REASONS FOR FAILURE OF TREATMENT.

1. The ulcer belongs to one of the exceptional types described in the earlier part of the article, and can be cured with N.A.B., diathermy, fungicides, etc.

2. The bandages are not applied tight enough, and here it is the patient who is often at fault rather than the doctor. She keeps up a steady appeal for

less pressure and the doctor yields. A little time spent in explanation will help this and convince her that there is no risk of cutting the circulation off completely.

3. Intermittency of treatment is the most ridiculous mistake. I have known the elastoplast bandages applied one week and ointment the next and the elastoplast again, and so on, and as a result the oedema is never controlled.

4. The bandage is not applied from toes to knee.

5. The various adjuvants to treatment are omitted, such as the pressure pads to coax indurated and malleolar ulcers to heal and the felt plaster and longitudinal strips to prevent cutting in larger ulcers.

6. Precautions to prevent recurrence are omitted after healing is obtained. This is largely due to the extravagant claims made for the injection treatment of varicose veins. These will only cure cases entirely when the deep veins are securely valved and sound. In other cases the question of prolonged or permanent support has to be considered, and also change of occupation.

7. Abandonment of treatment because of allergic eczema. The various substitutes mentioned will succeed when elastoplast fails.

Reviews

A TEXTBOOK OF GYNÆCOLOGY. Second Edition. By Arthur Hall Curtis, M.D. 1934. W. B. Saunders Company, Philadelphia and London. Pp. 493, with 300 illustrations. Price, 25s.

THE second edition of this well-known textbook has been published. There are many good illustrations, with explanatory notes; those depicting standard operations are particularly useful.

The method of arrangement of chapters appears new to one used to British and Continental textbooks. Tumours of the uterus have been discussed before 'Disturbances of Function'. It is a textbook and is presumably meant for students. It may be difficult for them to follow the sequence of description in this way.

Every chapter has been written in a very interesting manner and in simple style and much new matter has been incorporated. A great deal of the method and practice of gynæcology has been revolutionized by the great advances made in the realms of endocrine therapy. But in spite of all this advance, we agree with the author, when he says 'data obtainable from well-directed clinical experiment therapy might add greatly to our scanty knowledge of treatment. But blind administration of hormones brings harmful results'.

Chapter 42—The Early Months of Pregnancy (from a gynæcological aspect)—will be well appreciated by those for whom the book is meant. Tests for pregnancy are described and dangers of tubal insufflation and lipiodol tests are well brought to the notice of an unwary gynæcologist who is investigating the diagnosis of a pelvic tumour.

There is little new in the chapter on prolapse. There is, however, an excellent unbiased summary of the current ideas of operative and non-operative treatment of this condition. We unhesitatingly agree with the author when he says—'the Watkins-Wertheim operation is finding a more and more restricted field of usefulness in these cases'.

An elaborate summary of gynæcological pathology has been interposed in suitable places. Chapter 29—Physiology and Pathology of the Endometrium—is of particular interest because of the clear details and precise information that it contains. The mode of origin of endometrioma is discussed and Sampson's

theory—which, incidentally, is accepted by the author—is well illustrated in a nice diagram.

The author lays great stress on acquired or congenital obstruction of the cervical canal. Study of cervical erosions reveals to the author 'that a large percentage are actually devoid of an epithelial covering—the surface is composed of granulation tissue infiltrated with leucocytes'. From these opinions we differ.

The chapter on surgical technique has been well written. We read 'Recent experiments indicate that intravenous administration of glucose solution inhibits peristalsis of both the normal and the obstructed intestine'. Our experience fails to corroborate this statement.

Altogether this is a valuable book; the illustrations and the get-up are typically American; they are excellent. Modern views are set forth in a concise and interesting manner. The author has succeeded in bringing this work up to date and adding to the number of outstanding textbooks in the English language.

M. S.

A SYNOPSIS OF MEDICINE. Sixth Edition. By H. Letheby Tidy, M.A., M.D., B.Ch. (Oxon.), F.R.C.P. (Lond.). 1934. John Wright & Sons Ltd., Bristol. Pp. xvi plus 1112. Price, 21s.

THIS book has a very comprehensive scope. Of the thirteen sections the first is by far the largest, occupying 300 out of 1052 pages. The information regarding the various diseases dealt with in this section is a systematic compilation, some of it unfortunately gathered from textbooks which are not quite up to date. For instance *Atebrin* is not mentioned under malaria; under prophylaxis in leprosy it is stated 'segregation and isolation are unnecessary when sanitary conditions exist in the home'; while under yellow fever no mention is made of fixed-virus inoculation.

The sections on the various systems of the body should be of great value especially to the medical student, as a tremendous amount of compact information is compressed into a minimum of space. For the medical practitioner the chief value must be in recalling to memory subjects which have already been carefully studied from larger special works, for the amount of information given is by itself scarcely sufficient for either diagnosis or treatment.

As is stated in the introduction, this 'synopsis' cannot replace a textbook to the student, and any attempt to make it do so will inevitably lead to failure.

Yet for quick reference on almost all diseases, or as an introduction to the study of medicine especially for those with examinations in prospect, it is difficult to imagine a more useful production.

E. M.

THE BRITISH PHARMACEUTICAL CODEX, 1934.—

Published by direction of the Council of the Pharmaceutical Society of Great Britain. The Pharmaceutical Press, London. Pp. xxiii plus 1768. Price, 35s. Postage 1s. Foreign postage extra

THE aims of this publication are to provide authoritative information on all drugs in use whether these have been included in the British Pharmacopœia or not. It is published under the authority of the Council of the Pharmaceutical Society of Great Britain who appoint a large committee of experts to carry out the work, therefore the whole of its contents are thoroughly reliable. The Codex first appeared in 1907 and again in 1911, and a third time in 1923, the present edition making the third revision in twenty-eight years. It is accordingly very welcome, for the last eleven years have seen the addition of very many preparations to the list of medicaments and also a new edition of the British Pharmacopœia has recently appeared. Everything of value in therapeutics is embodied in the present edition so that it contains practically all that is in the British Pharmacopœia and a great deal in addition.

It is divided into four parts, the first being devoted to a description of drugs and their preparations, including all new organic preparations such as liver extracts, prophylactic and curative vaccines and sera, and also the vitamins, to mention only a few. This part occupies over 1100 pages. Part two describes surgical dressings and part three covers over 350 pages entirely devoted to formulæ and details of how to prepare the various drugs and their combinations. Part four is occupied with tables, giving weights and measures, atomic weights, chemical reagents and analytical tables. This enormous collection of valuable information is completed by a full index which gives after each name every page in the book on which the drug happens to be mentioned.

This book may be summed up as a necessity to all persons engaged in dispensing medicines, and of very great value to all those prescribing them.

NUTRITION AND DISEASE: THE INTERACTION OF CLINICAL AND EXPERIMENTAL WORK.—By E.

Mellanby, M.D., F.R.C.P., F.R.S. 1934. Oliver and Boyd, Edinburgh. Pp. xix plus 171. Illustrated. Price, 8s. 6d.

TO-DAY many laymen are aware of the significance and relationship of food to such diseases as rickets and scurvy. In these pages however the medical man will realize that the field of nutritional disease is increasing. The book contains six chapters dealing with rickets, dental structure and disease, the thyroid gland, nutrition and infection, and finally nutritional influences on the nervous system, two chapters one on experimental work and the other on clinical conditions. The matter in the latter part of the book will probably be quite new to many. The author's views on such diseases as beri-beri and lathyrism are obviously of profound importance in this country. The possibility of subacute combined degeneration of the cord and disseminated sclerosis having a nutritional factor opens up new fields of study. The general trend of the final chapters is the significance of vitamin A in relation to the central nervous system. The author wisely cautions one against thinking that this is the only factor in such diseases. The book is

easily read, extremely interesting, and should prove of value to practitioners especially in this country.

H. E. C. W.

RECENT ADVANCES IN ALLERGY (ASTHMA, HAY FEVER, ECZEMA, MIGRAINE, ETC.).—By G. W. Bray, M.B., Ch.M. (Sydney), M.R.C.P. (Lond.). Second Edition. 1934. J. and A. Churchill, Limited, London. Pp. xv plus 503, with 106 illustrations including four coloured plates. Price, 15s.

THE author has summarized and reviewed the whole subject of allergy in this little book. Each chapter is followed by a comprehensive list of references. As an up-to-date summary, the book will be very useful for those who cannot keep abreast with the fast-increasing literature on the subject, while the copious references will be helpful to the workers on allergy.

The first 190 pages of the book are devoted to a discussion of the general aspects of allergy. The remaining portion deals with the individual manifestations, such as asthma, hay fever, allergic coryza and allergic diseases of the skin. Cerebral and gastrointestinal manifestations of allergy, physical and drug allergy, allergic joint conditions, etc., have all been well dealt with.

The author has presented a very sound conception of the allergic state, or altered reactivity to varied substances in human beings. In all the cases an allergic basis is a common constant predisposing factor; this is generally inherited but may be acquired through tissue damage. In an individual possessing this predisposition the allergic symptoms are produced by the specific allergens; which are of an inhalant, ingestant, infectant, or injectant nature. The action of these specific allergens is, in most cases, stimulated by various non-specific non-allergenic causes. In some cases these non-specific causes may by themselves produce symptoms in a predisposed person.

There are certain statements in the text with which it is difficult to agree. For example on page 132 the author points out that from the statistical evidence he is forced to conclude that 'presence of active tuberculosis and asthma in the same patient is a rarity'. This statement is not only contrary to the reviewer's experience but is not entirely supported by the literature quoted by the author. On page 133 he quotes Manges and Hawley who found radiological evidence of tuberculosis in 18 per cent of 157 patients with asthma, Harkavy and Heheld who found x-ray evidence of pulmonary tuberculosis in 10 per cent of 400 patients with asthma, and Acton and Dharmendra who found evidence of tuberculosis in 15 out of the 79 cases of asthma with chronic lung damage. Again on page 191 the author asserts that 'the asthmatic syndrome generally occurs only in the presence of specific sensitization'. If this view were to be accepted a majority of cases of asthma amongst Indians would have to be classified under a different disease altogether, because it is in a minority of cases that specific sensitization is present.

These criticisms are, however, only expressions of a personal view-point and should not be taken as criticisms of the book as a whole. The author is one of the leading authorities on this subject and he has produced a book quite up to the very high standard of this unique 'Recent Advances' series.

D.

COMMON SKIN DISEASES.—By A. C. Roxburgh, M.A., M.D., B.Ch. (Cantab.), F.R.C.P. (Lond.). Second Edition. 1934. H. K. Lewis and Company Limited, London. Pp. xxxii plus 370, with 8 plates in colour and 128 illustrations in the text. Price, 16s.

THE fact that a second edition of this book has been called for within two years of its first appearance is evidence of its popularity, which in the reviewer's opinion is well merited.

The author has confined himself strictly to common skin diseases and has accordingly produced a handbook of great value to students and general practitioners. It is noted, however, that this edition has been slightly enlarged by the addition of several conditions omitted from the first. This we look on as a sign of robust health in this small book, and we hope that in subsequent editions it will continue to grow until it eventually reaches adult status in the form of a textbook of dermatology, for the author has a clear style of writing and presents his facts in an eminently practical manner which is well suited to the production of a larger book on the subject.

P. A. M.

THE PRINCIPLES AND PRACTICE OF NEUROLOGY.

—By A. Cannon, K.C.A., M.D., Ph.D., D.P.M., R.C.P.S. (Lond.), and E. D. T. Hayos, M.D., D.P.M., R.C.P. & S. (Lond.). 1934. William Heinemann (Medical Books) Limited, London. Pp. xx plus 333. Illustrated. Price, 25s.

THE 'Principles and Practice of Neurology' is an important and comprehensive work by several authors. Within the scope of 325 pages is collected an abundance of facts welded together with much skill into a well-balanced whole. The reader is most impressed by the mature judgment displayed by the authors. All the modern advances in knowledge on this subject have been carefully incorporated, and throughout there is the mark of great ability and a wide personal experience, which together with the literary quality of writing maintains the readers' interest.

The first 55 pages are devoted to clinical examination of the nervous system by Professor G. H. Monrad Krogh. In the next 270 pages follows a description of various nervous diseases, dealt with systematically from the point of view of ætiology, signs and symptoms, prognosis, course and treatment. The section on cerebral tumours could hardly be improved on in the allotted space. The description of the inflammatory diseases of the nervous system, pyogenic and non-pyogenic, is conspicuously full. The section on rare diseases showing neurological signs and symptoms is a very valuable addition.

This book should be read not only by neurologists but by general medical practitioners as well. As the book is meant by its authors to be of special value to students of psychology the psychiatric aspect of certain diseases has received rather detailed attention. The book is not over-burdened with illustrations which is an advantage, while those given are very helpful. The paper and printing are both excellent and it well deserves the reception accorded to it.

R. N. C.

AIDS TO PSYCHIATRY.—By W. S. Dawson, M.A., M.D. (Oxon.), F.R.C.P. (Lond.), D.P.M. Third Edition. 1934. Baillière, Tindall and Cox, London. Pp. vii plus 318. Price, 4s. 6d.

THIS little book has now passed into its third edition. As the author states in his preface to this edition, several sections have been rewritten and recent changes in the lunacy laws have received appropriate notice. Special sections are devoted to legal procedure in Scotland. One may deplore the somewhat inadequate treatment still accorded to convulsive seizures, especially in children, in view of the fact that the book is written partly to help the general practitioner. There are not many topics in general medicine on which the general practitioner is in greater need of instruction than the correct diagnosis and prognosis of 'fits' in children. Hence some reference to the work of Ewald Stier of Berlin, as well as to that of others, should at least have been made. Similarly, no mention is made of the important researches of Pavlov and Lashley, researches that seem likely to add very materially to our knowledge of the organic basis of mind. The author dismisses in a few

words the subject of the psycho-analysis of children thereby leaving the reader that is not acquainted with psycho-analysis in general with the impression that the psycho-analysis of children is a procedure identical with that of adults, when, as a matter of fact, the technique is wholly different. The reference to Dr. Morton Prince on page 275 might lead the reader to suppose that this eminent American psychiatrist is still living; very unfortunately for psychiatry he died some years ago. In spite of these minor defects the book is well adapted for either the medical student or for those who seek the Diploma of Psychological Medicine or other kindred degree.

O. B.-H.

HYPNOTISM IN THE TREATMENT OF DISEASES.—

By B. Layton Lloyd, M.B., D.P.H. 1934. John Bale, Sons and Danielsson, Limited, London. Pp. vii plus 44. Price, 3s. 6d.

IN this small booklet the author has put forward his reasons for the more extensive use of hypnotism in the treatment of diseases, particularly functional in origin, and in which emotions and psychical factors play the chief part. He goes so far as to say that he is able to produce deep hypnosis and a stage of anaesthesia. Under its influence he is able to perform operations such as opening of deep abscesses, extraction of teeth and even deep operations. By hypnotism he is able to differentiate between functional and organic disorders, since a functional disorder disappears after one or two sittings. The other diseases which can according to him be cured are paralysis, blindness, aphasia, amnesia, stammering, pain, pruritis, skin diseases, asthma, addiction habits, etc.

He suggests that research into the art of hypnotism will bring about a closer relationship between physiology and pharmacology more than the laboratory experiments have done. The basis of hypnotism treatment is that it influences the internal secretions of hormones and produces strong suggestions on the subconscious mind. Hypnotism is a very potent medium of treatment and therefore should be used more extensively in practice.

Whether one can accept all the assertions made by the author or not the book undoubtedly is interesting and is written in very simple and clear English. It would have been to the advantage of practitioners if the author had included a chapter on the practical methods of inducing hypnosis by hypnotic suggestion.

R. N. C.

Note.—We have been asked to publish the following note in regard to this book.—EDITOR, *I. M. G.*:—

CORRECTION

The statement on page 34 to the effect that a patient had eleven teeth filled at one sitting, under post-hypnotic anaesthesia, is not correct. I endeavoured to get in touch with the dentist before publication, but was not able to do so.

The dentist now confirms the statement that the anaesthesia was perfect, and that several fillings were below the margin of the gums, but adds that the fillings were done at several sittings.

This does not affect the principle; in fact it is a severer test for the patient to be able to go several times and get immediate and complete anaesthesia every time, than it would be if it only occurred once.

It is not easy to account for the patient's lack of precise knowledge; he knew he went several times, but thought the other visits were for scaling.

I can only assume that the anaesthesia was so complete that he could not tell what was being done.

This is the only statement of observed fact mentioned in the book which did not come under my personal supervision (I was present at the extractions), and although it does not alter the value of post-hypnotic anaesthesia, I am correcting this error at the

earliest possible moment because I will not tolerate inaccuracy.

Oct. 12, 1934.

LECTURES ON MEDICAL ELECTRICITY.—By Elkin P. Cumberbatch, M.A., B.M. (Oxon.), D.M.R.E. (Camb.), F.R.C.P. (Lond.). 1934. Henry Kimpton, London. Pp. viii plus 236, with 38 illustrations. Price, 6s.

THIS little volume by such a well-known author needs no commendation from me. It is a somewhat novel departure in scientific literature being written in conversational style. Following each description of experimental procedure comes a short summary of the principles established. This helps, not only to fix important facts in the reader's memory, but affords to the student a rapid and easy way of revising the whole subject.

The author is noted for his clear and easy style. This little volume is no exception in this respect. It is easy and interesting reading. The numerous diagrams will help the student to understand the more difficult parts.

The whole subject of electro-therapy including the use of infra-red and ultra-violet rays is covered, so the volume will repay perusal by the expert, as well as by the student and general practitioner.

J. A. S.

DEVELOPMENTAL ANATOMY: A TEXTBOOK AND LABORATORY MANUAL OF EMBRYOLOGY.—By Leslie Brainerd Arey. Third Edition, Revised. 1934. W. B. Saunders Company, Philadelphia and London. Pp. 593, with 547 illustrations, many in colour. Price, 27s. 6d.

IN this edition of the book the general arrangement of the subject-matter remains the same as before. viz, Part I deals with general development, Part II with the development of the different systems according to their germ layer derivation and Part III is a laboratory manual for practical work on chick and pig embryos. Parts I and II have been thoroughly revised and rewritten in places in order to incorporate the most up-to-date information on the subject. The references at the end of each chapter will be of great use to inquiring readers. The description of the developmental anomalies makes the subject an interesting reading. One hundred and eighty-one new illustrations have been added making a total of 1,188 drawings which are very instructive. The utility of such an increased number of drawings in a book on embryology cannot be exaggerated. The author in his usual clear and lucid style has dealt with the complex developmental history which will be much appreciated by his readers. Part III which deals with the practical work on chick and pig embryos will be of immense help to students interested in practical embryology. The get-up of the book is excellent.

N. P.

PUBLIC HEALTH IN INDIA.—By N. R. Dharmavir, F.R.C.S.E., L.R.C.P.E., L.F.P.S.G.I., D.P.H. (Cantab.). 1934. Rama Krishna and Sons, Anarkali Street, Lahore. Pp. ix plus 361. Price, Rs. 3

THIS is not in any sense a textbook on public health, nor does it refer to India as a whole but only to the Punjab and then mainly to the city of Lahore. It is made up chiefly of a series of lectures and addresses on varied topics, such as food, excretal disposal, infant ailments, personal hygiene and public health administration. There is in consequence a good deal of overlapping and repetition. The author was born and brought up in the Punjab and, after taking his medical degree at Lahore, proceeded to England where he spent nearly 29 years in continuous medical practice, being at the same time health officer of a town in Lancashire. On his return to the Punjab

he has interested himself in the social, economic and health conditions of his native province. He seems to find these conditions worse than when he left them. His description of the city of Lahore 40 years ago, he finds, still stands as true as it was then. The climate has not changed either, and Kipling's tale of the 'City of Dreadful Night', we take it, would also still apply.

He attributes these unsatisfactory conditions of affairs on the one hand to the continued poverty, ignorance and conservatism of the masses, and on the other (so we would judge from his chapter on public health administration) to the indifference and 'un-practicableness' of the sanitary authorities. He does not exactly indicate how the inertia of centuries is to be moved, nor how the economic and living standards are to be raised, but we gather that the methods of Mustapha Kemal Pasha meet with his approval, and he would advise a vigorous and ruthless application of suitable mandatory laws and by-laws.

There are several chapters on nutrition and food. The author would divide the inhabitants of India roughly into two classes, those who cannot get enough to eat, and those who, having the means to obtain a sufficiency, eat too much. He is an enthusiastic vegetarian. The chapters on infant care are good; those on excretal disposal, water, etc., are on usual lines. The book merits attention by the obvious earnestness and enthusiasm of the author for the welfare and uplift of his compatriots in the Punjab.

A. D. S.

PRACTICAL HISTOLOGY FOR MEDICAL STUDENTS.—By D. T. Harris, M.P., D.Sc., F.Inst.P. Third Edition. 1934. H. K. Lewis and Company Limited, London. Pp. 36. Illustrated. Price, 7s. 6d.

THIS laboratory book is designed and compiled as a guide to medical students desirous of obtaining a systematic knowledge in practical histological work. All the tissues of common laboratory animals and also of human subjects have been fully dealt with. Special methods of fixation, technique of section-cutting and staining have been concisely but explicitly noted. The salient features of each specimen have been briefly indicated. Blank pages have been provided for rough sketches and drawings of the specimens studied and for supplementary notes. The comparative studies of histological structures of organs and tissues of lower animals and human beings have been well arranged and somewhat exhaustively carried out. The clear impressions which are thus formed on the students' minds of the minute normal structures of the body cannot easily be effaced and will surely form a sound basis for the further study of the pathological changes which may occur in them in disease. The plates on the types of blood cells and the microphotography of pig embryos are very instructive. The usefulness of such a laboratory manual for practical histological work cannot be overestimated. The book is strongly recommended as a constant companion to those medical students who want to learn thoroughly the important subject of normal histology which is a basis of modern medicine.

M. N. D.

THE DIABETIC LIFE: ITS CONTROL BY DIET AND INSULIN.—By R. D. Lawrence, M.A., M.D., F.R.C.P. (Lond.). Eighth Edition. 1934. J. and A. Churchill, Limited, London. Pp. x plus 224. Illustrated. Price, 8s. 6d.

THE fact that the book has gone through eight editions within 10 years is by itself convincing evidence of its popularity and that it has been translated into four different languages speaks volumes in respect of its usefulness.

No fundamental changes have been introduced in the present edition except that the *line ration scheme*

has been modified to provide the present-day method of 'higher carbohydrate and lower fat' system of dieting.

We have no hesitation in saying that the book will be found to be as useful as before.

J. P. B.

BIOCHEMICAL AND ALLIED RESEARCH IN INDIA.

Issued by the Indian Institute of Science, Bangalore

THIS booklet although it covers only 76 pages contains a most comprehensive survey of the recent work carried out in biochemistry and allied subjects in India. To give one an idea of the width of the field an enumeration of the chapters is illuminating; they are, enzymes, agricultural chemistry, chemistry and agricultural industries, foods and nutrition of farm animals, dairy chemistry, vegetable physiology, phytopathology, medicinal and pharmaceutical chemistry, progress of research on nutrition in India including work on vitamins, chemistry, biology and sanitation. Several aspects of research deserve special notice such as dairy farming, feeding of cattle, human nutrition and sanitation. There can be no question of the inestimable value of a good, cheap and plentiful milk supply. It is all to the good of the people of India that work should be done on the food values of land produce for milk cows. The final chapter on sanitation contains some practical information on the purification of a water supply by copper sulphate which has been carried out in Madras. The pamphlet should certainly be consulted by all those interested in the wide field covered by biochemistry in India to-day.

H. E. C. W.

HEALTH NOTES FOR YOUNG MEN OVERSEAS.

Published by the British Social Hygiene Council Incorporated, London. Pp. 34. Price, 4d.

THIS small pamphlet has been prepared by the British Social Hygiene Council with the intention that it should be given to young men proceeding overseas, especially to tea and rubber and other plantations. It is a small booklet enclosed in a stiff water- and insect-proof cover and its price is negligible. Though it is marked 'Health Notes for Young Men Overseas', its page title inside is 'Notes on the Venereal Diseases', and it deals entirely with these matters. The subject is dealt with in a straightforward manner and nowadays there can surely be no objection to this. The venereal diseases and their dangers are described and the importance of prevention and early treatment stressed. Methods of disinfection are described and their efficacy discussed. The booklet finishes up thus: 'It would seem, therefore, wise and expedient—however hard may be the circumstances—to decide to wait for the time when the sex impulse can be expressed in a marriage of affection, without the deceit, anxiety and danger of non-marital relations'.

Perhaps the dangers of the extra ounce of alcohol, as Col. Harrison calls it, which often throws prudence and good resolutions to the winds might have been stressed more. The words of the old servant Adam in 'As You Like It' might be oftener heard and acted on—

'For in my youth I never did apply
Hot and rebellious liquors in my blood
Nor did not with unbashful forehead woo
The means of weakness and debility'.

Every adult is the arbiter of his own conduct, but he should be forewarned and advised.

A. D. S.

Abstracts from Reports

A SURVEY OF Aedes MOSQUITOES IN BOMBAY AND THE MEASURES SUGGESTED FOR THEIR CONTROL. BY DR. R. K. MHATRE, L.M.&S. (BOM.), D.P.H., D.T.M.&H. (CANTAB.), OFFICER-IN-CHARGE, MALARIA BRANCH, PUBLIC HEALTH DEPARTMENT, BOMBAY MUNICIPALITY

IN view of the importance at present attached to the probable spread of yellow fever to India and other countries by aircraft the following abstract is of considerable historical interest showing that the public health authorities of over twenty years ago were no less alert than they are to-day, and it is interesting to note that Dr. Bentley the recently retired Director of Public Health of Bengal was one of the active participants in this early campaign.

PART I

Early history of protective measures against yellow fever

IN 1907 Sir Patrick Manson gave a warning about the possibility of yellow fever being introduced in the Eastern countries on completion of the Panama Canal. Real interest in this subject was, however, evoked in India by a paper read by Major Gordon Tucker, 'Yellow fever, India's future danger' before the Bombay branch of the British Medical Association in June 1910. It was anticipated that after the opening of the Panama Canal an increasing commerce would commence from and through the principal endemic centres of yellow fever to the seaports of China and the East.

Of the three endemic areas of yellow fever, Equatorial America, the West India Islands and a small part of

the West Coast of Africa, it was feared that yellow fever would be introduced into Eastern countries from Equatorial America and the West India Islands through the canal traffic.

Regarding the epidemiology of yellow fever, Gordon Tucker pointed out that it was essentially a disease of the warm climates and was chiefly restricted to seaports, the maximum prevalence of the disease following maximum temperature and latitude 22° north and south of the equator roughly covering its area of maximum intensity. He further stated that the key to the epidemiology of yellow fever, including its propagation, locality, seasonal variation and prevention, had been found in the virus's extra-corporal host—*Stegomyia fasciata*. On the authority of Dr. Bentley he stated that *Stegomyia fasciata* was of common occurrence in Bombay. Realizing that two of the three factors necessary for yellow fever epidemics, *Stegomyia fasciata* in abundance and a completely non-immune population being already available and having in view the possibility of the virus being admitted into any of the Eastern countries in the route mentioned in his paper, he gave a warning that we could not flatter ourselves that the risk of infection of Asiatic ports was 'very remote'.

In order that some steps should be taken to ward off the introduction of yellow fever into Eastern countries before the Panama Canal was opened for traffic and to cope with the disease in case it found its way into India, Gordon Tucker made the following suggestions, viz:—

(1) that an International Conference should be held for a campaign against *Stegomyia fasciata* in the centres where the disease was endemic;

(2) that medical officers should be encouraged to study the clinical side of the disease in its endemic area; and

(3) that the great ports of India such as Bombay and Calcutta should be entirely cleared of mosquitoes, so that if infection were to arrive it would find no carriers.

The Government of Bombay before submitting the matter for the information of the Government of India obtained the opinions of the Health Officer of the Port of Bombay and the Sanitary Commissioner for the Government of Bombay.

Lieutenant-Colonel Jennings, Health Officer of the Port of Bombay, suggested the following as the only practical measures which were likely to minimize or avert the danger:—

(1) The rendering of all vessels calling at or starting from infected ports mosquito free.

(2) The use of curtains and mosquito proofing of doors and other openings in cabins.

(3) Vigorous measures to exterminate mosquitoes in ports in which the disease was endemic.

(4) A constant campaign against mosquitoes along the proposed canal and particularly at the ports at either end thereof.

(5) Inspection at definite ports on the main line of route with a view to protecting suspicious cases from bites of mosquitoes (there being no fear in the case of well-established cases, as the virus existed in the peripheral blood during the first three days of the attack).

(6) A campaign against mosquitoes at all ports along the line of route and in India.

(7) The preparation of a protective vaccine.

(8) Experiments to discover some means of anointing the skin which will be protective against mosquitoes.

Lieutenant-Colonel Dyson, Sanitary Commissioner for the Government of Bombay, maintained that defensive measures against the introduction of yellow fever would be too irksome and expensive, and by no means reliable and advocated a direct attack on the disease in its endemic homes. In furtherance of this object, the first step suggested by him was the formation of a Convention of the Powers concerned, not for the purpose of legislating for the sanitary control of shipping coming from infected ports, nor for the protection of threatened ports, but with a view to organizing and financing a campaign against yellow fever in the endemic areas.

In March 1911 the matter was referred to the Government of India who replied that they fully realized the importance of the matter and that they intended, with the sanction of the Secretary of State, to depute Major S. P. James to attend the International Conference on the subject held at Hongkong in January 1912, and from there to study the disease in the endemic area. They also agreed with the Bombay Government that it was desirable that medical officers should be encouraged to study the clinical aspects of the disease in the endemic area.

Major James submitted his report to the Government of India in 1913. A copy of the report was received by the President, Bombay Municipal Corporation, in May 1913, through the Government of Bombay. This report dealt mainly with the measures to be taken outside India. The recommendations in regard to these measures were:—

(1) Appointment of medical officers as intelligence officers in ports outside India.

(2) Institution of scientific enquiries under the auspices of the Royal Society.

(3) Establishment of a Central Intelligence Bureau.

(4) A modern quarantine station at Hongkong.

(5) Port Health rules regarding yellow fever to be brought into line with modern knowledge and arrangements made for the destruction of mosquitoes on ships.

These recommendations being primarily of Imperial concern, the Government of India addressed the Secretary of State on the subject and requested him to take the necessary steps.

As regards India itself, James made the following recommendations, viz:—

(1) The systematic investigation in India of the *Stegomyia* problem according to a definite scheme and the continuous improvement and extension of further constant water supplies.

(2) An enquiry into the possibility of the spread of the disease to India by way of the Cape of Good Hope.

In regard to the proposal for a systematic investigation in India of the *Stegomyia* problem, James submitted at the same time a 'Note on the practicability of *Stegomyia* reduction in Indian seaports'. From his observations it seemed clear to him that the key to the problem of reducing *Stegomyia* mosquitoes in Indian seaports lay in the water supply. Although all the seaports which he had examined were provided with a piped water supply, there was not one in which the arrangements were such as to obviate the necessity of water storage in houses, and the receptacles used for such storage were the chief breeding places of *Stegomyia fasciata*. In Bombay the supply was intermittent and the pressure was insufficient to provide a tap supply in the upper storeys of the houses. There were usually three or four storage cisterns in each of the larger houses, one being on the roof, the others often in dark inaccessible corners under staircases. On the ground floor there was often a stone reservoir and nearly always a well. Smaller receptacles for storing water were numerous. Cisterns erected on the pavements for the purpose of supplying the road-watering carts were also a prominent feature of the city.

The remedy suggested by him for overcoming the necessity of storing water in houses was the provision of a constant high pressure water supply, and this measure was, in his view, the first step that should be taken in any attempt to reduce *Stegomyia fasciata* in our seaports.

Later on, in 1916, Lieutenant-Colonel Jennings, Health Officer of the Port of Bombay, in his report on the Indian Ports Act with reference to the precautions to be taken at Bombay against yellow fever, recommended, in view of the many interests involved, and of the fact that the arrangements would have to be permanent, that the whole question be referred for report to a select committee.

The Government of Bombay approved of the suggestion made by the Port Health Officer that a committee should be appointed to consider the arrangements to be made for a site and accommodation for the isolation of the passengers and crews subjected to surveillance under Rule 32 of the Port Rules relating to yellow fever, and the committee which was appointed was asked to report within two months.

The Government of India deputed Major Christophers in December 1919 to investigate the prevalence of *Stegomyia* mosquitoes in the neighbourhood of all possible land sites for a quarantine station, prior to the consideration of the subject by a technical advisory committee.

This committee, appointed by Government order, submitted a report on 15th December, 1919, which was based on the recommendations made by Major Christophers regarding a suitable place for the quarantine station.

In February 1920 the Government of India summoned a committee at Calcutta to consider measures for the prevention of yellow fever in India. The policy to be pursued in connection with this was based upon:—

(1) precautions outside India;

(2) the protection of the principal Indian ports from infection by—

(a) the extermination of *Stegomyia* mosquitoes;

(b) the imposition of a strict system of modified quarantine.

Dr. K. E. Dadachanji, a representative of the Bombay Municipal Corporation, was appointed on the committee. The following were some of the important conclusions arrived at by the committee:—

(1) The prevalence of the mosquito *Stegomyia fasciata*, which transmits the yellow fever virus, and the existence of a susceptible population in the chief seaports of India indicate that the introduction of this disease might be followed by sudden virulent outbreaks.

(2) *Stegomyia fasciata* is present in India as in almost all maritime regions situated within the parallel 40° N. and 40° S. and all ports within such limits must be regarded in the present state of our knowledge as liable in varying degree to introduction of the disease and its dissemination.

(3) The committee is of opinion that the existing arrangements in the main ports of India are wholly inadequate to prevent the introduction of dangerous epidemic diseases and considers that at each of the important ports of ocean call a sanitary station should be established.

(4) The committee is of opinion that no possible advantage is to be gained from the establishment of sanitary stations on islands distant from the ports they have to serve.

(5) In recommending sites for sanitary stations the committee finds, in the case of Bombay, Butcher Island as the one site satisfying all requirements of such a station.

(6) In addition to the five main ports, there are on the coast line of India some 196 ports, 104 of which are in the Madras Presidency and 75 in the Bombay Presidency. In the case of some of these ports, vessels, the majority of which appear to be sailing ships, trade with ports in the Straits Settlements and in East Africa. The committee recommends that a sanitary survey of these ports, including accurate information relating to the trade relations of each, and mosquito infestation be made at an early date. It will be then possible to decide to what extent these ports contribute to the risk of the introduction of dangerous epidemic diseases, especially yellow fever, to India, and what measures are necessary to meet such danger.

(7) The committee is of opinion that the most effective method of protecting the ports of India from yellow fever is to keep them as free as possible from *Stegomyia* mosquitoes, and that it is undesirable to separate the work required for the reduction of *Stegomyia* from that of mosquito reduction generally. Mosquito control can be carried out by a properly directed organization working under a legally constituted sanitary authority. The committee therefore recommends that Government legislate:—

(1) to appoint a sanitary authority for each port;

(2) to establish a properly directed organization for the control of mosquitoes in each of the larger seaport towns;

(3) to provide for contributions from Government revenues towards the cost of these schemes;

(4) to secure the efficient carrying out of these measures in the event of failure on the part of the local authority.

For the sake of efficiency as well as economy it is desirable that adjoining local authorities should prepare a conjoint scheme.

After these resolutions of the committee were passed in 1920, nothing particularly interesting appears to have happened in regard to these recommendations until now.

An enquiry was made in 1927 by the Executive Health Officer, Bombay, as regards the progress made since 1920 with the Trans-Continental Railway in Africa and, in connection with this, the Public Health Commissioner with the Government of India obtained the necessary information from the Colonial Office, London. It was stated that no project for the construction of a railway across Africa was engaging the attention of the Government of any British Colony or Protectorate in Africa.

The Colonial Office added that it might be interesting to know, with regard to the general question of the protection of India against yellow fever and other dangerous epidemic diseases, that the question of yellow fever in West Africa was being studied by a commission organized by the International Health Board and that this commission had been at work in West Africa since May 1925.

Since 1927 the Municipal Commissioner, Bombay, has been writing to the Bombay Government almost every year enquiring whether any progress has been made with the establishment of a sanitary station in Bombay and in the carrying out of the other recommendations made by the committee appointed by the Government of India to consider the question of preventive measures against the importation of yellow fever into India.

The last communication to this effect was made in February 1933 to which a reply was received that the Government of India had not passed any orders as regards the establishment of a port quarantine station in Bombay, as the question was linked with the general question of the administration of major ports on which no decision had been arrived at by that Government. Similar replies had been received to the previous communications.

Further development in regard to this subject was evinced at the Regional Health Conference of the League of Nations held at Cape Town in November 1932. One of the principal subjects discussed was the prevention of the spread of yellow fever. India was represented at this Conference by Major-General J. W. Graham, Public Health Commissioner with the Government of India, who submitted a report of the work done at the Conference. According to him, it was agreed at the Conference that further *Aedes* survey work was desirable, and that considerably more active *Aedes* control should be undertaken than is at present the case at points in infectable countries which may be considered to be particularly vulnerable to the introduction of yellow fever infection.

The object of tracing this history is to obtain a clear idea about the several recommendations made in regard to the adoption of preventive measures against yellow fever since the note of warning was sounded in 1907 by Manson and to know how we stand at present as regards the protection of Bombay and other seaports against the importation of the disease. The history of the events recorded above shows that Bombay and incidentally the whole country is in exactly the same unprotected state against the disease to-day as it was a quarter of a century ago. Luckily the virus of the disease has not up to now been introduced into the East.

Part II is devoted to the present position and the following abstracts will be seen to contain useful information regarding dangerous places, distances, and times of air travel in Africa.

Within the last few years the situation in regard to communication between West and East Africa has been greatly altered owing to the modern development of mechanical transport. It is possible now to cross the country from West to East by air, rail or motor car. It is said that motor tours from West to East Africa and back are being advertised. By any of these means of transport the journey from an endemic area of yellow fever in West Africa to an East African seaport can be completed within the incubation period of the disease. The incubation period of yellow fever in man is from three to six days, and he is infective to the mosquito during the first three days of his illness. Thus a person contracting the infection in West Africa may at any time land in any of the seaports on the East coast during the incubation period and develop the disease there. If the infection of yellow fever spreads in this way from its natural home in West Africa to the East coast, the favourable conditions for its dissemination existing in the seaports will lead to epidemics. Once the disease is firmly established on

investigation in regard to the action of venoms and, particularly, anavenoms.

SUMMARY OF THE REPORT ON THE SESSION OF THE OFFICE INTERNATIONAL D'HYGIENE PUBLIQUE HELD IN PARIS, 30TH APRIL TO 9TH MAY, 1934, BY LIEUT.-COLONEL J. TAYLOR, D.S.O., M.D., D.P.H., I.M.S., DIRECTOR, CENTRAL RESEARCH INSTITUTE, KASALI, AND DELEGATE FOR THE GOVERNMENT OF INDIA

The session was a very active one and accomplished work of high value. The problems in which India was specially interested received detailed attention and the results of the discussions will assist in settling several questions which were put before the committee.

The report of the Quarantine Commission on the alleged importation of plague into Peru by the agency of jute cargoes from Calcutta should assist in the removal of the restrictions on such cargoes which have been imposed by the government of that country.

The opinions on the suitability of oral vaccine for the prevention of cholera during the pilgrimage, which were expressed by the committee, indicate that this method will not be acceptable. The report on the use of single-dose inoculation with cholera vaccine and the dosage to be employed shows that the methods recommended are in exact accordance with the practice and experience in India.

The countries which had formerly adopted varying periods for vaccination against smallpox and cholera have now conformed to the terms of the International Sanitary Convention for Aerial Navigation with the exception of Persia whose intentions are not yet known.

The subject of preparation of a standard cholera diagnostic serum has now advanced to a stage at which it is considered that further work on the subject can only be effectively carried out in countries such as India where facilities exist for conducting investigations during the presence of epidemics and great reliance is placed on India to continue investigations on this point and in other matters in regard to cholera. Lines of work have been suggested.

A question of considerable importance has been raised on the interpretation of the terms of Article 38 of Section II of the Aerial Convention in relation to areas in which mouse protection tests have shown immunity to yellow fever while no cases of the disease have been recognized. The attitude of countries towards aeroplanes coming from such areas will require to be considered in the event of anti-amaryl aerodromes not being provided in these areas.

The recommendations of the committee on standards for fumigation with sulphur will form a valuable guide to the practical application of this method.

The revision of the 'personal card' for the treatment of venereal diseases in seamen will ensure a greater regularity in treatment.

The communications on technical subjects presented are of high value to workers in special subjects.

THIRTY-FIRST ANNUAL REPORT OF THE BUREAU OF SCIENCE, PHILIPPINE ISLANDS, FOR THE YEAR ENDING 31ST DECEMBER, 1932. BY WILLIAM H. BROWN, DIRECTOR OF THE BUREAU OF SCIENCE

Good progress was made during the year along various lines of research, in spite of the greatly reduced appropriation. Perhaps the most important investigations were those on rice bran and mango blossom blight. The work on rice bran, which was mentioned in my previous report, is now largely completed, and it has been found that rice bran is very nutritious and has an excellent vitamin content, being superior in these respects to wheat bread or rice. It can be cooked in a great variety of ways such as bread, cookies, and breakfast cereal. This

bran should prove to be an exceedingly valuable food in rice-producing countries and its judicious use would go far toward eliminating beri-beri, which is a terrible affliction in all regions where polished rice is consumed.

In the Philippines mango trees bear fruit rather scantily on account of the attack of leaf hoppers which cause mango blossom blight. It has been found possible to control this blight easily and cheaply and to produce good crops of fruit. This investigation should make it possible to produce mangoes in such quantities and at a price which is low enough so that they can be preserved commercially in various ways.

Medical biology.—The distribution, transmission, immunity, hæmatology, and treatment of rat-bite fever in Manila was investigated. The cases of rat-bite fever which were registered in 1931 and those of bubonic plague during the years 1912 to 1914 had practically the same distribution in Manila.

Doctor Garcia and Miss Rita Villaamil continued the work initiated by Dr. Otto Schobl on the purification of the antidyenteric serum prepared in the serum laboratory of the Bureau of Science with the view of eliminating the anaphylactic effects which sometimes follow the use of the unpurified serum. The results so far obtained are encouraging.

Organic chemistry.—Philippine soybean and talisay oils were investigated. The results showed that these were edible oils of high quality. The fatty oil from different varieties of rice was also investigated. The results showed these rice oils were also edible oils of high quality.

Food preservation.—Work was continued on methods of using soya bean in the Filipino diet and many suitable dishes were devised, and a very large number of recipes for the use of rice bran were prepared. A considerable number of native fruits were preserved by the freezing method. Mangoes proved unusually well adapted to this method, and are already being prepared in this way on a commercial scale and find a ready market. A number of fruits were candied and prove to be very popular. Particularly good were preparations made from mangoes and papaya. In addition to candies, a considerable number of products with commercial possibilities were made from green papaya. These include imitation apple sauce, imitation apple butter, and papaya sauer kraut. A large number of fruits and vegetables were dehydrated successfully while excellent juices were prepared from a lot of others. Some of these have distinct commercial possibilities. Many popular native dishes were successfully canned.

Experiments by Dr. Russell with avian malaria demonstrated that plasmochin will not prevent the infection of birds with the sporozoites of malaria. These experiments and those of 1931 have shown quite clearly that plasmochin is an excellent therapeutic drug but that it has no direct lethal effect on the infective sporozoites as they are injected into the blood stream by a mosquito.

Want of space prevents us abstracting further from this interesting report. We have limited our abstract to matters of medical interest only but practically every branch of human activity is dealt with in this bureau so that persons interested in such widely differing subjects as railroad construction, chemistry, zoology, and all aspects of public health (to mention only a few branches) will find information of value.

ANNUAL REPORT ON THE WORKING OF THE ASSAM MENTAL HOSPITAL, TEZPUR, FOR THE YEAR 1933. BY COLONEL J. P. CAMERON, C.S.I., C.I.E., V.H.S., I.M.S., INSPECTOR-GENERAL OF CIVIL HOSPITALS, ASSAM

Dr. Chowdhury underwent special training for six months at the Ranchi Mental Hospital prior to assuming charge as whole-time medical superintendent of the Tezpur Mental Hospital.

The Civil Surgeon, Darrang, now acts as consultant to the hospital.

The number of inmates remaining at the end of the year 1932 was 628, of whom 523 were males and 105 females. During the year under review 153 patients (131 males and 19 females) were admitted, including eight re-admissions, all of whom were males. The total number of patients treated during the year was, therefore, 781 (657 males and 124 females) as against 18 (601 males and 117 females) in 1932.

Of this number, 70 were discharged 'cured', 11 discharged as 'improved', 1 discharged as 'not improved' and 22 died, leaving 677 at the end of the year.

The percentages of recoveries calculated on the daily average strength was 10.79 against 4.77 in 1932. Thirty-nine cases of alleged lunacy were admitted during the year, including 3 re-admissions, for observation and 2 cases were carried forward from the previous year; of these 26 were certified insane.

Cultivators and tea garden coolies furnished the greatest number of admissions.

There were 22 deaths during the year under review against 52 in 1932. This gives a death rate of 3.39

the daily average strength against 8.53 in 1932 which is very satisfactory.

The chief causes of death were dysentery and tuberculosis, the former disease being responsible for 14 deaths and the latter for 10.

Encouraging results were obtained by the use of prophylactic dysentery bilivaccine, which was administered to all the inmates.

Special accommodation is available for patients suffering from tuberculosis, so that complete segregation can be effected.

Male patients are employed on cultivation of vegetables and sugar-cane, manufacture of *gur*, jute, fencing of garden land, cane and bamboo works, carpentry, masonry and the usual domestic services. Females are employed on paddy husking, preparation of spices, mending clothes and other household works. Weaving is done by both male and female patients.

The special methods of treatment adopted were hydrotherapy, special dieting—including artificial feeding in cases exhibiting active refusal of food—occupational therapy, organotherapy and a trial of sulfoxin in a few cases of dementia praecox.

The hospital garden continues to do well, yielding some profit and a useful addition to the dietary.

The accommodation available at the end of the year, including all types of ward cells and infirmaries, was for 566 males and 124 females—or a total of 690.

The maximum number confined in any one night during the year was 684 against 634 in 1932.

The health of the inmates was satisfactory during the year and the sick and mortality rates compare favourably with those of the previous year. The usual prophylactic measures were adopted against smallpox, dysentery and cholera.

The superintendent has again put forward proposals for additional establishment. One temporary clerk has been sanctioned recently, but the request for additional keepers (10 males and 3 females) has not been sanctioned. To avoid recourse to mechanical restraint it is essential for this additional establishment to be provided.

The institution was successfully managed during the year by Dr. Chowdhury and his staff, and the health statistics go to show that the medical supervision was very satisfactory.

THE FOURTEENTH ANNUAL REPORT OF THE
BLIND RELIEF ASSOCIATION, BIJAPUR, 1933.
BY R. V. MONE, M.R.C.S., D.T.M., B.M.S. CLASS
I, CIVIL SURGEON, AND CHAIRMAN, BLIND
RELIEF ASSOCIATION, BIJAPUR

We have pleasure in once again drawing attention to the valuable work being done by this association, which is clearly indicated in the abstract below.

Those persons interested may obtain copies of this report and send subscriptions to the Civil Surgeon and Chairman, Blind Relief Association, Bijapur (M. & S. M. Railway).

Medical staff.—The association has two subordinate medical officers. Both work under the civil surgeon who is also the chairman of the managing committee of the association and does some portion of the operative work at headquarters. Both are Government servants kindly lent to the association.

During the year the touring medical officer paid on an average four visits to each taluka, the maximum being six and the minimum three in different groups of villages, inspected and examined the work of field workers and operated on suitable cases in suitable places. He had fifteen operation camps collecting such operation cases as were unable to go to the civil hospital. He was given greater facilities this year and owing to financial stringency he had to perform operations which could be conveniently tackled by him in camps and taluka places while on tour. This has saved the association travelling expenses and diet money required to be spent on patients brought to headquarters till about six months ago. The touring medical officer also visited Akalkot state and the state authorities have to be specially thanked for the facilities given by them to him when camping in the state. We cannot but mention here of the benevolent attitude of Her Highness the Dowager Rani Saheb, the state darbar and the authorities in the state for their generous grant which has enabled the association to entertain a special field worker for its work in the state.

Field workers.—There are eleven field workers employed by the association.

The association also carried on its work in Jath, Jamkhandi and Ramdurg states for some time but owing to financial stringency and non-receipt of grants from them it had to discontinue its work in these states.

The field workers have been specially trained at the headquarters in elementary diseases of the eye and its appendages by the medical officer in sub-charge of the eye wing. They know how to handle cases, wash the eyes and apply some remedies. While under training they get a good working knowledge of the various common eye diseases and know exactly when a case is serious and when a patient should be sent to hospital.

They have to tour round the number of villages given in their charge and maintain a pony for the purpose. They are supplied with a medicine chest containing, among other things, solutions of silver nitrate of different strengths, boric acid, sodium chloride, mercury ointment, argyrol, a bowl and a tray and some cotton-wool to wash the eyes.

They maintain a register in every village showing the names of all cases treated by them at every visit. The number of new cases treated by them during the year came to 15,820, and the number of repeated treatments was 3,651. Besides these a separate account of the more chronic cases requiring repeated treatments for a fairly long time, such as blepharitis and trachoma, and the number of treatments adopted in such cases for the first time came to 4,264 and that of repeated treatments to 7,614. Of these 2,346 were on school children. These figures clearly show what a large amount of work is being carried out in the district.

The field workers inspect the eyes of newborn children. The number of infants so inspected from house to house during the year under report for the first time, within ten days of birth, was 3,223 and that of repeated inspections within ten days was 585. The number of infants inspected ten days after birth, for the first time, was 23,353 and that of repeated visits after this, up to one year of age, was 39,036. The actual number of ophthalmia neonatorum cases found and treated during the year under report was only six

SPENCER FORCEPS

DR. GORDON SPENCER writes:—'When operating for entropion I found that Ratnaker's forceps could not be used in a large number of cases because of their prominent apex, which, owing to the atrophy which occurs at the fornix of trachomatous cases, rendered their proper adjustment impossible. I therefore had a pair of forceps made with the triangular portion much reduced and made round instead of triangular.'

These forceps again were not satisfactory because when they were adjusted and screwed up it was impossible, when putting in the stitches after having performed Snellen's operation, to bring the needle out below the ciliary margin.

Messrs. Down Brothers then made to my design the forceps illustrated above.

These forceps have the following advantages:—

1. The rounded blade enables them to be fitted into any eye no matter how small the conjunctival sac.

2. Access is obtainable into the extreme angles of the lid usually the points of most marked entropion. A much longer incision can be made than if Snellen's or Desmarre's forceps are used.

3. The instrument can be used for either eye so that only one forceps is necessary and not two.

4. Bleeding is as satisfactorily controlled as by the use of any other forceps, and there is no interference with the needle in putting in any form of stitches.

5. The instrument can be used for any operation on the lid for which the other forms of forceps are applicable, *i.e.*, Heisricht's, etc.

6. The forceps are made in several sizes so that they can be used for lids of different sizes.

The forceps have now been used for over 1,000 entropion operations and have proved entirely satisfactory.

THE 'COMPLETE G. P.' BAG

THE exigency of modern practice demands of the doctor, when visiting a case, a complete armamentarium

for dealing with emergencies and for providing urgent treatment.

This bag has been designed and used for three years by a doctor with a large mixed practice. In its present form it embodies the results of his experience as to the essential requirements necessary to obviate delay. It is of compact size and easily carried, yet containing a full equipment.

This bag is so arranged that every item is immediately visible and accessible the moment the lid is lifted. This object is achieved by the bag being made

to open at the top and to be used in the upright position as it is carried. The front of the bag need only be let down to get at the compartment holding the emergency dressing, etc. No spilling or disorder can occur, there being a definite place for everything provided. The large central space is to hold the folding stethoscope, and room is left for further instruments, such as a sphygmomanometer.

The measurements of the bag are 13½ inches by 6½ inches by 9 inches.

It is manufactured by Messrs. C. J. Hewlett and Son, Ltd., 35 to 42, Charlotte Street, London, E.C.2 and the price is very reasonable.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*,' Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

CORNEAL TRANSPLANTATION ON OPAQUE CORNEAS*

By E. O'G. KIRWAN, F.R.C.S.I.

LIEUTENANT-COLONEL, I.M.S.

Professor of Ophthalmology, Medical College Hospitals, Calcutta

THE operation of keratoplasty is not new; it was attempted quite frequently in the past, but with very disappointing results. The first successful case was reported by Zinn in 1906, but successes have been very few.

In recent years, with the improvement in technique, corneal transplantation has aroused more enthusiasm as a number of successful cases have been reported by Elschnig in Prague and Tudor Thomas in England.

Various methods of procedure have been described. The lamellar and total keratoplasties have now been discarded, and the partial penetrating graft is the only one left.

DURING the months of December and January the hole press in which the *Indian Medical Gazette* is printed was moved to a new building. In these circumstances the editor feels that the printers have earned our congratulations rather than our censure by bringing out the January and February numbers each only one week later than the usual date. Next month we hope that we shall be able to return to our normal date of publication, i.e., the 10th of the month.

aqueous escapes, the trephine is laid aside and the attached portion of the graft removed with a fine pair of scissors. It is better not actually to remove the graft until the eye of the receiver is ready for its reception. The trephine used on the eye of the receiver should be a little larger than that used on the eye of the donor. The trephines used by me are 4 millimetres and 5 millimetres in diameter respectively.

The excised graft is lifted with a spatula or on the scissors from one eye to the other and great care should be exercised that it is not bruised. The less the manipulation of the graft, the less will be the haziness of the cornea, and the greater the ultimate success. The importance of placing the graft in the proper position with the corneal epithelium uppermost need hardly be pointed out. It is better to put the silk sutures which are to retain the graft before trephining the opaque cornea. Two silk sutures are inserted in a cartwheel form and tightened up when the graft is in position.

paper read at the meeting of the British Medical Association held in the School of Tropical Medicine, Calcutta, on the 9th November, 1934.

There is no necessity to put anything between the graft and the stitches.

On completion of the operation, sterile liquid paraffin drops are instilled into the conjunctival sac and both eyes bandaged. The patient must be kept in the recumbent position, the eye that was operated upon is opened on the third morning, atropine drops instilled, and both eyes kept bandaged for a week. The stitches are removed on the fourth day. At the end of a week the other eye is allowed to remain open and the patient permitted to sit up. It is better to keep the affected eye bandaged for three weeks.

Indications

The most favourable cases for operation are the corneas that show dense scars after interstitial keratitis. Congenital syphilis is usually the cause, but before keratoplasty is carried out vigorous treatment with arsenic and bismuth for at least one year must be given. It is not necessary to wait till the Wassermann reaction is negative, as this may remain positive for years in spite of treatment. Every effort

should also be made to clear the cornea as far as possible by the application of yellow mercuric iodine and dionine ointments. Keratoplasty is also indicated in the case of corneal opacity resulting from burns or ulceration, but should not be done sooner than one year after inflammation in the cornea has subsided. It should not, however, be carried out in cases of glaucoma. It is not advisable in children, as anaesthesia under local anaesthesia is not possible; the patient will not keep quiet.

Before operation is advised, great care should be taken to find out that there is good perception and projection of light and by transillumination to ascertain that there are no anterior or posterior synechiae.

The graft

This can be taken from the eye of a young or old person, with a normal cornea. It is immaterial whether the other parts of the eyeball have pathologically altered, or whether the eye has glaucoma or hypertension. It is advisable, but not essential, for the donor and the receiver to belong to the same blood group. As a rule, a slight haziness of the graft occurs during the first week after operation. This clears up usually in the second or third week. After four weeks one will usually know whether the cloudiness is permanent or not; permanency is evidenced by the appearance of vascularization in the implant. In successful cases, a ring of thick scar tissue is formed in the first few weeks after operation around the circumference of the graft. The periphery of the cornea in many cases often clears up tremendously as a result apparently of the graft setting up a biologic irritation. This more often occurs in cases of scars caused by interstitial keratitis,

A graft that remains clear for six weeks, according to Elschmig, never becomes opaque.

Summary

Keratoplasty or corneal transplantation is a very important part of plastic surgery, especially in India where blindness is so common from scars the result of interstitial keratitis and ulcers of the cornea. One has only to visit the outpatient department of the Eye Infirmary, Medical College, Calcutta, to appreciate this.

The operation is not difficult and the results are full of promise, provided that the minutest details in the technique are adhered to, and bearing in mind that success depends entirely on preserving the transparency of the delicate graft.

The following two cases of corneal transplantation on opaque corneas recently performed by me are described below :—

Case 1.—P. D., a Hindu girl, aged 16 years.

Previous history.—About four years ago, the girl developed a severe form of interstitial keratitis in both eyes and received a prolonged course of anti-syphilitic treatment.

The patient was admitted into hospital on the 5th July, 1934, with total loss of vision in both eyes.

General condition.—There are the characteristic signs of congenital syphilis present such as marked frontal bosses, Hutchinson's teeth, and depressed bridge of the nose. The Wassermann reaction was now negative.

Right eye.—The cornea was scattered with patches of opacities which involved the deep layers. The pupil could be seen clearly, there was evidence of old iritis and the lens was cataractous. The cataract was removed, the posterior capsule needled, and the vision was improved up to 5/60 with glasses.

Left eye.—The whole of the cornea was opaque and nothing of the deeper structures below could be seen. The vision was—perception and projection of light only.

The left eye was chosen for the keratoplasty as there was no area of clear cornea. The operation was carried out on the 24th September. The graft was taken from the cornea of a man of 25 years whose left eye had to be enucleated as a result of a penetrating injury near the limbus. Later, the eye developed iridocyclitis and was now totally blind and painful. When the eye was being removed, the wound gaped, there was an escape of vitreous and, as a result, the eyeball became soft. This added to the difficulty of taking a corneal graft from the eye.

A graft of the whole thickness of the cornea was then removed with a trephine of 4 millimetres diameter, the margins being cut shelving, the remainder of the graft being separated by excision with the scissors. A few drops of sterile warm liquid paraffin were then put on the graft which was not disturbed from its original position. The eye of the receiver was next anaesthetized with cocaine, and, after preliminary sterilization of the conjunctival sac, a circular hole with a 5-millimetre trephine was made on the opaque cornea over the centre of the pupillary area. It will be noted that this trephine was one millimetre bigger than the trephine used to remove the graft. After removal of the opaque disc, it was found that the lens was cataractous and there was much pigment deposit on the anterior capsule of the lens. The graft was then removed from the donor and placed in position and fitted excellently. The graft was kept in position by cross-stitches arranged

(Continued at foot of next column)

ON THE RELATIONSHIP BETWEEN THE QUININE CONCENTRATION IN THE CIRCULATING BLOOD AND PARASITE COUNT IN MONKEY MALARIA

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)
LIEUTENANT-COLONEL, I.M.S.

S. K. GANGULI, M.B.

and

A. C. ROY, M.Sc.

(From the Department of Pharmacology, School of Tropical Medicine, Calcutta)

INTRODUCTION

In a previous paper Chopra, Roy and Das Gupta (1934) reported the results of their

(Continued from previous column)

in a cartwheel fashion. The stitches were removed six days after the operation when it was found that the graft had taken well and appeared to be quite clear. There was very little reaction of the eye after the operation.

A month after the operation the graft was found to be well in position. Examination with the corneal microscope showed a haziness in the deeper layers, but there was no difficulty in seeing the outline of the pupil and the cataractous lens. There was a well-established anterior chamber. The patient states that she can see daylight brighter than before. It is now hoped to do an iridectomy followed by removal of the lens, and I have every hope that her vision will be improved.

Case 2.—N. G., a Hindu girl, aged 20 years (see plate I).

Previous history.—About two years ago the girl developed an attack of interstitial keratitis in the right eye. She had early anti-syphilitic treatment and the left eye was not involved.

Condition on admission.—The patient was admitted into hospital on the 18th September, 1934, complaining of total loss of vision in the right eye, resulting from the previous inflammation. The Wassermann reaction was found to be negative.

Right eye.—The whole of the cornea was opaque, the iris and pupil could not be seen, the tension was normal, the vision—finger movements only.

Left eye.—The cornea was clear, the pupil active, tension and vision normal.

Treatment.—Keratoplasty on the right eye was carried out on the 5th October. Difficulty was found in obtaining a proper donor and, as the girl was anxious to leave hospital, the graft had to be taken from an old man, aged 80 years, whose eye was removed for absolute glaucoma associated with great pain. The technique of the operation was the same as described in the previous case. When the opaque disc was removed, the pupil was found to be dilated, the lens was present and was seen to be quite clear. The stitches were removed six days after operation, the graft was found to be lying in a good position, flat with the surface of the cornea and was quite transparent. A month after the operation the graft had changed little.

On 5th November the patient's vision was 6/60; she could count fingers from the other end of the room and could read large print.

Examination with the corneal microscope.—On the same date the pupil and the surrounding iris could be easily seen; there was evidence of old iritis in the form of pigment spots on the anterior capsule of the lens. There were no blood vessels to be seen in the graft.

This case is remarkable in the fact that the corneal transplantation was taken from a donor of 80 years of age, and it is also of interest to note that he belonged to a different blood group.

PLATE I.

Case No. 2.

Before Operation.

After Operation.

investigation on the concentration of quinine attained in the blood at different intervals of time after administration of the drug by the oral, intramuscular and intravenous routes. They showed that the concentration of quinine in the blood after administration by these different channels runs almost parallel. Taking the average of all estimations the maximum concentration in the blood was found after 15 minutes, both following intramuscular and intravenous injections; the average figures for blood drawn after half an hour and one hour respectively were about the same, and the concentration in specimens of blood drawn after two hours and onwards showed a gradual fall, the intramuscular figures being somewhat higher at this stage than the intravenous ones; the concentration reached within the first two to three hours after administration by the oral route was in some cases distinctly lower.

The next point in our investigation was to determine whether any relationship existed between the concentration of quinine in the circulating blood and the parasite count at any particular moment. In clinical practice the relationship between concentration of quinine and parasites in the blood appears to be very variable. This may be due to virulence of malarial parasites, variations in the susceptibility of individuals, or to variations in the concentration of quinine in the blood of patients receiving the same therapeutic dose. James (1931) observed that in induced malaria there is always a tendency on the part of every individual to clear his system of malarial parasites when given slight assistance, *e.g.*, with quinine. He stated that even large doses of quinine (30 grains) given during the incubation period have no effect; a dose of 15 grains given on the first day of the attack has little effect; one of 5 grains given in the middle of the course stops the fever at once and greatly reduces the number of parasites, but the same dose when given at or near the end of the course and repeated once a day for a few days cures 50 per cent of the cases. Bass (1930) stated that the quantity of quinine necessary for treatment of malaria varies very much in different individuals. As little as 5 grains daily may be sufficient in some cases, while in others 10 or 12 grains may be required; 30 grains daily always suffice to control symptoms as quickly and surely as larger doses.

In view of these observations a series of experiments were performed on monkeys to determine whether with the maximum concentration of quinine obtained in the blood the parasites exhibited any tendency to increase or decrease in number, or to show degenerative changes. *Silenus rhesus* monkeys were infected with strains of *Plasmodium knowlesi* from another infected monkey, as in our previous experiments, and the erythrocyte and the corresponding parasite counts were determined.

Quinine was then administered by the intramuscular or the intravenous route, and the concentration of the alkaloid in the blood and parasite counts were simultaneously determined at stated intervals. Although quinine was administered daily for 2, 3 or 4 days, on account of the difficulty of getting sufficient quantities of the blood, simultaneous counts and estimations of quinine could not be done every day. The results of these experiments are given in the table.

DISCUSSION OF RESULTS

Intramuscular series.—A perusal of the table will show that in monkeys I, II and III quinine was given intramuscularly. In monkey I the quinine concentration reached the maximum limit in about half an hour and remained more or less constant during the first 4 hours, but the number of parasites in the peripheral blood actually increased during the first 24 hours; the parasites were reduced in number gradually and after 48 hours the count was 24,200 and the monkey recovered. In monkey II there was no appreciable change in the number of parasites nor any evidence of degeneration in them when quinine concentration was at its highest. After 48 hours the count increased to 222,500 per c.mm. but subsequent treatment, *i.e.*, two more injections of quinine, controlled the infection and the animal recovered. In monkey III the parasite count actually increased to above one million per c.mm. within 4 hours of administration of quinine and proved fatal on the third day in spite of the fairly high concentration of quinine maintained in the blood. It is also to be noted that in monkeys II and III the concentration of quinine attained in the blood was small in comparison to that in monkey I; this demonstrates a fact that has already been noted by Chopra and others (1934) who found that there was a good deal of individual variation regarding the concentration of quinine attained at different intervals of time after administration of similar amounts. While in one monkey the maximum concentration may be attained in less than half an hour and maintained for some time, in others an equally high concentration never develops.

Intravenous series.—In monkeys IV, V and VI quinine was given intravenously. In monkey V there was no change in the number of parasites on the first day; the count came down after 24 hours, but the animal died on the fifth day showing scanty parasites in smears of blood. In monkey IV the parasite count was more than doubled within 4 hours of quinine injection and in monkey VI 24 hours after the injection the count increased from 497,250 to 1,317,500. In these two cases, in spite of a high concentration of quinine in the blood, the parasites actually increased in number till the count in both cases reached a

Showing parasite count per c.mm. and quinine concentration in the blood expressed in mgm. per 100 c.cm. at stated times in plasmodium-infected monkeys that had received $1\frac{1}{2}$ grains of quinine daily

Serial no.	Before injection	AFTER INJECTION					Route and number of doses	REMARKS
		1 hour	2 hours	4 hours	24 hours	48 hours		
I								
Parasite count	346,200	501,300	642,000	604,150	94,400	24,200	Intra-muscular, 4 days	At the end of 48 and 72 hours, just before the second and third injection, the quinine concentration was 0.4 and 0.2 respectively. Recovered.
Quinine concentrations	..	1.05	0.90	1.00	0.45	..		
II								
Parasite count	60,840	56,000	53,000	50,000	55,000	222,500	Intra-muscular, 4 days	Infection was controlled and monkey recovered.
Quinine concentrations	..	0.90	0.50	0.30	0.10	..		
III								
Parasite count	349,050	537,000	805,500	1,020,300	700,400	490,000	Intra-muscular, 2 days	Died.
Quinine concentrations	..	0.75	0.70	0.35	0.20	..		
IV								
Parasite count	513,600	617,500	701,800	1,524,250	345,200	634,400	Intravenous, 2 days	Died on third day. Quinine concentration 1.2 half an hour after second injection.
Quinine concentrations	..	1.00	1.30	0.90	0.25	..		
V								
Parasite count	187,200	163,800	163,000	140,000	80,000	..	Intravenous, 4 days	Died on fifth day; smear from heart blood showed scanty parasites.
Quinine concentrations	..	1.60	1.20	0.90	0.20	..		
VI								
Parasite count	497,250	585,000	500,000	731,250	1,317,500	605,000	Intravenous, 3 days	Died on third day. Quinine concentration 1.2 half an hour after second injection.
Quinine concentrations	..	1.00	0.70	0.65	0.20	..		

figure of over one million per c.mm., a condition which is invariably fatal.

It will be seen from the above that both in the case of intramuscular and intravenous injections no relationship was found to exist between the maximum concentration of quinine in the blood and the number of parasites therein. The infection, as a rule, was not controlled before two or even three injections were given at daily intervals, no matter what was the concentration of quinine in the blood. If any change in parasites was observed, it was an increase in their number immediately after the injection, but never a marked decrease. This is in conformity with the previous findings of Chopra, Das Gupta and Sen (1932) who, describing a fatal case of severe malignant tertian malaria, reported that when malarial infection is heavy, no antimalarial remedy, by whatever route it may be given, appears to be of any avail. The first effect of administration

of quinine is often a definite increase in the number of parasites in the blood.

Mode of action of quinine.—This brings us to the important question of the mode of action of quinine on malarial parasites. If quinine has a direct toxic effect on the malarial parasites, then our aim in treatment would be to obtain as high a concentration of quinine in the blood as possible and to maintain it for a sufficient length of time; but evidence at our disposal does not warrant the view that a high concentration of quinine will have an immediate and direct lethal action on the malarial parasites. Kirschbaum (1923) succeeded in producing malaria by injection of blood containing parasites, which had been set aside for 24 hours after mixing with quinine in concentration of 1 in 10,000, a concentration far greater than it is possible to attain in the circulation. Again Ramsden, Lipkin and Whitley (1918) reported that in certain cases they found the quinine

content to be the highest and symptoms of cinchonism greatest in those in whom the parasites persisted the longest. Acton (1921) expressed the opinion that a quinine concentration between the limits of 1 in 150,000 and 1 in 250,000 is lethal to the malarial parasites only when maintained for a sufficient length of time, and that lesser concentrations have no effect.

These experiments show that quinine, even in high concentration, has no direct lethal action on *P. knowlesi* in monkeys. Moreover a high concentration of quinine cannot be maintained for a considerable length of time in clinical practice because of the rapid excretion of the drug. The drug has been found to cure malarial infection in monkeys, even though the concentration of quinine in the blood may not be high, provided this infection has not progressed beyond a certain limit. Some evidence has been brought forward here to show that concentration of quinine in the blood is not the only factor in bringing about a cure, as no direct relationship has been found to exist between the quinine concentration in the blood and the parasite count in these experiments. Even when the concentration of quinine in the blood was the maximum attainable after administering the largest possible therapeutic dose, the parasites did not show any tendency to reduction in number nor was there any evidence of degenerative changes in them. On the other hand, there was a definite increase in number in most of the cases (I, III, IV and VI).

It has already been stated that the parasitidal action of quinine is manifested when the concentration in the blood varies between 1 in 150,000 to 1 in 250,000. Such a concentration and even higher ones were maintained for several hours in all our experiments, but the parasite counts did not show that it had any immediate effect on the parasites. The question naturally arises what other factors are concerned in the action of quinine besides the concentration of the alkaloid. Chopra and Choudhury (1929) showed that in the circulating blood quinine causes a lowering of the surface tension resulting in greater concentration of quinine at the various interfaces of the cell walls. The enhanced activity depends on this lowering of surface tension and also in part on the increase of the negative charge of the cells. As a result an alteration in the electrical condition of the parasites occurs which leads to their ultimate destruction. An interesting point in connection with the mode of action of quinine has been put forward by Krishnan (1933) who states that the usefulness of quinine is chiefly dependent upon the degree to which the natural process of immunity is stimulated, e.g., by accelerating the mobilization, proliferation and functional activation of the phagocytic large mononuclear cells of the

reticulo-endothelial system, and not upon the quantity of the drug or its direct lethal action on the malarial parasites. How far other mechanisms of protection, such as the inhibition of the reproductive activity of the parasites and the formation of specific antibodies in the host, are responsible for cure of malarial infection is beyond the scope of the present investigation, but the available evidence at our disposal seems to indicate that, even with the highest possible concentration of quinine in the blood, the activity of the parasites is not very greatly retarded. The action of quinine is probably synergistic to other defensive mechanisms set up in the body. The administration of quinine in therapeutic doses would appear to augment these processes, or possibly it acts on the parasites in such a way as to render them more vulnerable or unable to propagate.

SUMMARY AND CONCLUSIONS

1. The concentrations of quinine attained in the blood at various intervals of time after administration of the alkaloid and the simultaneous parasite counts are given in a small series of monkeys infected with *Plasmodium knowlesi*.

2. It has been shown that there is no direct relationship between the concentration of quinine in the blood and the parasite count at any particular time. The highest concentration of the alkaloid attainable without producing too severe toxic effects produces no apparent reduction in the number of parasites, nor degenerative changes in them. On the other hand in the majority of cases there was a definite apparent increase in the number of parasites per c.mm. of blood after administration of quinine.

3. The action of quinine on the parasites does not appear to be direct, but is probably synergistic to other mechanisms set up in the body.

4. It has been observed that once the number of parasites approximates to one million per c.mm. no amount of quinine, however administered, is of any avail.

THE VENEREAL ORIGIN OF GRANULOMA INGUINALE*

By T. BHASKARA MENON, M.D. (Mad.)

M.R.C.P. (Lond.)

Pathologist

and

P. NATESAN, M.B.B.S.

Assistant Venereologist, Government Rayapuram Hospital, Madras

A CAREFUL analysis of the history of cases of granuloma inguinale very often reveals the incidence of a primary lesion on the genitalia in the form of a small pustule. This finally bursts and leaves a small non-indurated ulcer which often heals but breaks down again. One of us (Bhaskara Menon, 1933) has drawn attention to this feature in the history of cases studied in the General Hospital and the Government Rayapuram Hospital, Madras. In a series of patients, the primary lesion was followed by cicatrization and deformity of the prepuce and the patients came into hospital for circumcision. The subsequent history of these cases showed that the circumcision wound did not heal, but continued to break down till all the clinical features of granuloma were reproduced. In other instances, the sore had healed, but had broken down again and the granuloma had developed. The site of the lesion itself is, in most cases, the genitalia, and ulceration of the groin is secondary to spread of infection from the genitalia. It has been argued by Nair and Pandalai (1934) that lack of a primary involvement of the cervix and the vagina is against a venereal origin. But the fact that the organism attacks moist stratified surface epithelium of muco-cutaneous junctions and lives inside epithelial cells is enough to explain this feature. The soft epithelial cells of mucous membranes probably do not afford a footing for the organism.

In sections stained by the Weigert-Gram method, the crowding of the organisms inside the surface epithelial cells can be demonstrated. The implication of the mononuclear cells and intracytic multiplication is a later stage in the spread of the inflammatory process.

The following three illustrative cases reveal very strong evidence of a venereal origin, besides indicating different stages of the disease:

Case 1.—Mr. A. M. K., a young Hindu of twenty-six years, was admitted to the venereal department of the Government Rayapuram Hospital, Madras, on the 3rd August, 1933, for an ulcer on the penis. The history was that the patient had a sore on the same situation six months previously. It had healed after a month's treatment, but had broken down again previous to admission. There was a definite history of exposure to infection one month prior to the development of the first ulcer. It had started as a small painless boil which had burst and had become

an ulcer. On admission, the patient had two small ulcers, each of the size of a four-anna piece, on the under surface of the prepuce near the frenum (figure 1). The ulcers themselves looked soft and vascular and they bled readily on manipulation. The base was

Figure 1
Case 1.—Showing the primary lesion on the frenum and prepuce. Stage I of granuloma inguinale.

soft and there was no induration. There was little pain and there was not the angry-looking inflamed appearance of soft sore. The glands were just palpable. The dark-ground examination was negative and the Wassermann reaction was also negative. An examination of the smears showed typical intracellular forms of the Donovan body. On treatment with urea stibamine the ulcer completely healed.

Case 2.—Mr. V. S., a young Hindu of thirty years, was admitted to the venereal clinic of the Government Rayapuram Hospital, Madras, on the 15th September, 1934. He was a resident of Nellore and had come down to Madras for treatment. He was married five years ago and his wife Mrs. P. A. was an in-patient in the venereal ward on the 13th October, 1933, and subsequently on the 7th September, 1934, for inguinal granuloma. Her case records show that the Donovan organisms were demonstrated. He himself denied all illicit intercourse. There was a definite history of exposure to infection with his wife two months prior to admission. The present condition developed a month after exposure as a small pustule on the right side of the frenum. This gradually became an ulcer.

On admission the condition was one of paraphimosis, with an oblong granulating ulcer, about 2 inches by 1 inch, extending from the meatus on the ventral aspect of the glans over the paraphimotic prepuce (figure 2). There were a number of small papular elevations all round the ulcer. The ulcer itself was indolent, not very painful, soft to the touch and covered with granulations. There was very little discharge. The groin glands were not enlarged. There were no cutaneous lesions, suggestive of syphilis; there was no discharge from the urethra. The dark-ground examination was negative, the Wassermann reaction was negative, but the Kahn test was positive. A smear from the ulcer showed typical intracellular

* A paper read at the Indian Science Congress at Calcutta in January 1935.

forms of the Donovan organisms. Treatment was carried out by intramuscular injections of a 7 per cent solution of the trivalent antimony compound Fouadin.

Figure 2

Case 2.—Showing the granulomatous ulcer with secondary nodules all round. Stage II of granuloma inguinale.

The ulcer completely healed after one month's treatment.

Case 3.—Mr. L. N., a young Hindu of the Komati caste, coming from Nellore district, was admitted to

Figure 3

Case 3.—The chronic well-developed lesion—granuloma genito-inguinale. Stage III.

the Government Rayapuram Hospital, Madras, in May 1934, for extensive ulcerating granuloma involving the genitalia and groins. This was of five years' duration. A careful study of the history of this case showed that, five years ago, the lesion started as an ulcer on the frenum ten days after sexual exposure. This had gradually spread around the prepuce. Circumcision was done at the Government Hospital at Ongole as the ulcer in the penis was healing and breaking down again. He remained in hospital for a month and was discharged when the wound had healed. There was a small ulcer which had developed at the root of the penis; and this had not healed. This gradually spread on to the groin on both sides and also on to the skin of the scrotum. He had been under Ayurvedic treatment for the last five years. There was no history of gonorrhoea. *Two other people who exposed themselves to infection with the same woman got similar types of ulcers, but these had healed with Ayurvedic treatment and that was why the patient persisted with this treatment for such a long period.* He was admitted into the General Hospital, Madras, where, under a course of injections, the ulcer had gradually healed but had broken down again, after discharge from hospital.

On admission, the patient had an ulcer on both sides of the groin, extending all round the root of the penis and leaving only a small area of healthy skin on the anterior aspect of the organ. The ulcerated areas in the groin had also spread across two inches above the root of the penis, forming another communicating ulcer. The whole ulcer was $6\frac{1}{2}$ inches long and $3\frac{1}{2}$ inches wide and had an irregular serpiginous margin. The base was covered with protuberant granulations which showed a few bleeding points. There was an oblique scar extending across above the ulcer, $3\frac{1}{2}$ inches long and 1 inch wide. The scrotum was extensively involved, except at the posterior part.

The dark-ground examination was negative, the Wassermann reaction was negative and Frei's test also negative. An examination of the smear showed Donovan organisms.

Discussion

In case 1 we have an instance of the primary lesions which healed and broke down again. In most cases, in our studies, this primary lesion appeared as a small pustule about three to four weeks after sexual intercourse. The pustule breaks down and becomes converted into a shallow ulcer in about a week. There is no induration. There is very little pain and the discharge is only slight, unlike a soft sore. The ulcers are sometimes multiple. In most cases, there is a definite history of healing followed by subsequent breaking down of the ulcer. Very often there is ulceration at the root of the penis or of the skin of the scrotum, probably by auto-inoculation. The involvement of the moist sodden skin of the genito-crural folds is, in our experience, always a secondary event. In earlier studies, one of us (Bhaskara Menon, 1933) raised the question whether granuloma venereum could be regarded as a secondary infection to some other lesion, such as a soft sore on the genitalia; but subsequent work has shown that the primary sore itself is, to some extent, distinctive and could be differentiated from soft sore. The ulcer is indolent in type, there is no angry-looking inflamed base, there is very little pain and no marked involvement of the lymphatic

glands. Examination at this stage has shown that Duerey's bacillus cannot be demonstrated, but the typical intracellular forms of the Donovan body can be found in smears from the surface, as in case 1, if a careful search is made for the organism.

In case 2 we have an instance of a more advanced type of lesion, following the primary sore. This may be regarded as the second stage of the disease with persistence and chronicity of the penile lesion. The picture here is that of a well-developed granuloma with commencing secondary nodules, all round a chronic granulomatous ulcer confined to the glans and prepuce. The definite venereal history in this case is one that cannot easily be refuted.

In case 3 we have a picture of the well-defined and typical lesion in what might be called the third stage of the disease. Here the granuloma has spread to the groin and there is extensive involvement of the penis and scrotum. The definite venereal history in this case and the history of a similar disease in two other people, though not directly confirmed, reminds one of the case of Mary X, as recorded by Stoddart, when the syphilitic origin of general paralysis was demonstrated.

Summary and conclusions

Our views regarding the venereal origin of granuloma inguinale are re-affirmed. Three illustrative cases are recorded showing the three stages of the disease: a primary lesion, a second stage with the commencement of the granulating lesion with secondary nodules, and a third stage with an established chronic lesion—granuloma genito-inguinale.

In our experience, a careful analysis of the history of cases of granuloma inguinale would reveal a venereal history in a large proportion. In others, there are extra-genital lesions and these can be explained as due to extra-genital inoculations, as in syphilis.

Acknowledgment

We are indebted to Mr. C. R. Krishnasamy, M.S., venereologist of this hospital, for permission to study and report these cases. We are also indebted to Dr. D. R. Annamalai for the careful study of the history of case 3.

THE EFFECT OF THE USE OF LIVING OR DEAD SUSPENSIONS OF VIBRIOS ON THE AGGLUTINATION TITRE

By RICHARD W. LINTON, Ph.D.

and

S. C. SEAL, M.B.

(Cholera Inquiry, Indian Research Fund Association; All-India Institute of Hygiene and Public Health, Calcutta)

In referring to cholera vibrio agglutination reactions in a recent paper (1935), we stated that 'if the antigens are old or have been killed by heat the agglutination titres of many vibrios are sometimes greatly reduced or may even be absent'. In the case of a strain which we used to illustrate this statement it was found that after it had been killed by heating at 60°C. for half an hour it had become inagglutinable with antiserum with which it agglutinated at 1:1,000 when living.

This observation was of interest not only in its bearing on the structure of the vibrios, which was the point of view from which we had approached it, but also in the practical use of the agglutination reaction for the diagnosis of cholera. We have accordingly studied it further.

Antisera against the following strains were used:—

'Rangoon smooth' and 2027, which are typical vibrios isolated from cases of cholera;

W880, a vibrio isolated from water, which does not agglutinate at all or only very slightly with anti-cholera sera;

El Tor, an agglutinating vibrio of human origin not found in a case of cholera;

and 'Rangoon rough' (2) an extremely rough non-motile variant of 'Rangoon smooth'.

These were set up against the strains named in the table which in addition to those already mentioned comprise:—

vibrios 1617 and 505, which are strains isolated from cholera cases;

'Rangoon rough' (1), a rough vibrio isolated from the same case as 'Rangoon smooth';

and 'Rangoon rough' (2a), a smoother vibrio isolated from the extremely rough 'Rangoon rough' (2).

The killing of the vibrios was carried out by heating them for half an hour at 60°C. in the water bath. The suspensions were of a concentration of approximately 2,000 million per c.cm. before dilution with equal amounts of the diluted antisera. Readings were made after 4 hours at 56°C. and again after the tubes had stood overnight in the ice-box. The titres given represent the dilution in the tube showing at least '1-plus' agglutination; 'plus-and-minus' readings were neglected, as also were titres below 1:50.

The results are given in the following table:—

yet in general the higher titres are given when living vibrios are used. The difference is

TABLE

Effect on the agglutination titre of the use of living and killed suspensions of vibrios

Antisera	Vibrios	Titre when killed suspension is used	Titre when living suspension is used
'Rangoon smooth'	'Rangoon smooth'	1,600	12,800
	1617	400	1,600
	'Rangoon rough' (1)	0	200
	2027	0	2,000
	505	0	1,000
	W880	0	0
	'Rangoon rough' (2a)	500	5,000
2027	El Tor	500	800
	'Rangoon smooth'	400	1,600
	1617	200	400
	'Rangoon rough' (1)	0	0
	2027	3,200	6,400
	505	800	3,200
	W880	100	100
W880	El Tor	400	400
	'Rangoon smooth'	0	400
	1617	50	50
	'Rangoon rough' (1)	0	0
	2027	200	200
	505	0	800
	W880	12,800	12,800
El Tor	'Rangoon rough' (2)	50	0
	El Tor	50	200
	'Rangoon smooth'	50	0
	1617	400	500
	'Rangoon rough' (1)	0	0
	2027	0	50
	505	0	0
'Rangoon rough' (2)	W880	0	0
	El Tor	3,200	4,000
	'Rangoon smooth'	0	0
	1617	0	0
	'Rangoon rough' (1)	0	0
	2027	0	0
	505	0	0
	W880	0	200
	'Rangoon rough' (2)	200	25,600
	El Tor	0	0

A consideration of the table shows that 'Rangoon smooth' antiserum agglutinates its own strain at eight times greater dilution when living organisms are used. In the other cases where this antiserum was studied (except that of the El Tor strain), the titre with living organisms is also significantly higher, and in the case of three vibrios, apparently inagglutinable organisms are found to be agglutinable when living vibrios are being tested. This finding is of interest since two of these strains (2027 and 505) are from cases of cholera and the antiserum is also against a cholera vibrio. In spite of this combination, however, if killed suspensions are used these two organisms appear to be inagglutinable.

In the case of 2027 antiserum the differences in the two sets of suspensions are less marked,

especially marked in the cholera vibrios 'Rangoon smooth' and 505.

The antiserum against the water vibrio W880 reaches a titre of 12,800 with its homologous organism whether this is living or dead. Two of the cholera vibrios, 'Rangoon smooth' and 505, are definitely agglutinable when their suspensions are used in the living condition, and as definitely inagglutinable when the emulsion is that of killed vibrios.

With the El Tor antiserum there are practically no differences between the two sets of experiments.

'Rangoon rough' (2) antiserum does not agglutinate any of the heterologous strains when these have been killed. When living emulsions are used it gives a definite reaction

OBSERVATIONS ON THE VITAMIN-A
VALUE OF HALIBUT-LIVER OIL

By B. AHMAD, Ph.D.

*From the Department of Biochemistry and Nutrition,
All-India Institute of Hygiene and Public Health,
Calcutta*

SINCE the work of Karrer, Morf and Schöpp (1931), at Zürich, and of the British

(Continued from previous page)

chemists in Liverpool and London (Heilbron, Heslop, Morton, Webster, Rea and Drummond, 1932) on the isolation of vitamin A from halibut-liver oil, the latter has been regarded as one of the richest natural sources of vitamin A. Emmet, Bird, Nielsen and Cannon (1932) examined a number of different samples and observed that this oil was 75 to 125 times richer in vitamin A than the standard cod-liver oil and at the same time it was the richest known source of vitamin D. Commercial interests have not failed to exploit these findings and halibut-liver oil has been widely advertised as a better and more potent substitute for cod-liver oil. On account of its high potency in fat-soluble vitamins it has the advantage that it is required to be taken in a much smaller dose than cod-liver oil which very often is not very readily taken by children. Halibut-liver oil is expensive but it is claimed that, value for value as a source of vitamins A and D, it is cheaper than cod-liver oil.

with W880 vibrio, but with none of the others. Its behaviour with its homologous organism is noteworthy: a titre of 1:200 with killed organisms and of 1:25,600 when the same organisms are used in the living condition.

In general, it may be said that the use of living vibrio suspensions has the advantage of giving agglutination to higher titres, and even at times of allowing agglutination to occur where otherwise it would not. On the other hand, when an antiserum like W880 is being used, there may be some loss of specificity with living suspensions, in that vibrios from cases of cholera, like 'Rangoon smooth' and 505, may agglutinate with it. However, this situation is not likely to occur in routine agglutination tests, where antisera to known cholera vibrios are being used, and in experimental work both kinds of suspensions may be used. Living suspensions seem to possess a distinct advantage over dead suspensions in the vibrio agglutination test.

Recently, halibut-liver oil has found its application in general clinical practice in India. During the last few months it was brought to our notice by some local medical practitioners that in their experience infants and children, whose lack of normal growth they believed to be due to a dietary deficiency, did not respond so well to halibut-liver oil as they did to cod-liver oil. Indeed in one case, where prolonged administration of halibut-liver oil had failed to produce any beneficial effect on the general health of the child, the administration of cod-liver oil resulted in an immediate response—an increase of weight.

At our suggestion two samples of halibut-liver oil which had failed to show any results in clinical tests were brought to this laboratory for examination as to their vitamin potency. Colorimetric tests for vitamin A were made and it was found that though the values were somewhat less than those claimed by the importers, they were 35 to 40 times more potent than an average sample of imported cod-liver oil (giving 6.0 'blue units' in 10 per cent solution). Similar complaints had been brought to the notice of Dr. B. C. Guha (private communication) but when he proceeded to test a number of samples of halibut-liver oil by the colorimetric test, the values were not found to be very seriously lower than was expected. Our own observations and those of Dr. Guha, therefore, gave rise to the suspicion that probably the colorimetric test was giving higher values than the actual vitamin-A content of the oil, and possibly a chromogen other than vitamin A was present in halibut-liver oil.

The observation that moderate heating lowers agglutinability is an old one. The current explanation of this variability is that the heat-labile flagellar 'H' antigen is injured or partially destroyed by the heat. It is in fact highly probable that some change in the vibrio surface is brought about by the application of a temperature of even 60°C., but whether this change is in the flagellar portion of the vibrio alone or whether the whole organism is modified slightly by heating is as yet an unanswered question. It is clear that the strains we have studied do not all act in the same way when heated to the same temperature, since some of them lose their agglutinability entirely while others have the same titre as in the living condition.

Whatever may be the actual basis for the differences in agglutination between living and dead organisms, it is our purpose here only to call attention to the practical importance of the use of living cultures in the cholera agglutination reaction, as otherwise cholera strains may be labelled as inagglutinable when as a matter of fact they are agglutinable. Our work has shown that such confusion can arise with strains from cases of cholera.

REFERENCE

Linton, R. W., Mitra, B. N., and Seal, S. C. (1935). *Indian Journ. Med. Res.* In the press, April 1935.

In view of these observations we have tested a representative sample of halibut-liver oil both colorimetrically and biologically. This sample was very kindly supplied to us by Dr. B. C.

Gnha. The results of these tests are described below :—

Colorimetric tests

This test was carried out according to the technique of Carr and Price (1926). 1.0 grammes oil was dissolved in chloroform and the volume made up to 250 c.cm. 0.2 c.cm. of this solution was mixed with 2 c.cm. of antimony trichloride reagent and the colour estimated after 30 seconds in a Lovibond tintometer. This gave a value of 9.5 blue units. In 10 per cent dilution the value would be $9.5 \times 25 = 237.5$ blue units.

Biological tests

The usual technique was employed using young albino rats as the test animal (Ahmad and Drummond, 1930). After 3 to 4 weeks on the vitamin-A-free basal diet their weights began to decline and they showed typical growth curves indicating depletion of their vitamin-A reserves. Then supplements of halibut-liver oil were fed for $3\frac{1}{2}$ to 4 weeks. The results of these tests are summarized in the following table :—

Rat no.	Sex	Dose of halibut-liver oil (mg.)	Total time of test (days)	Total change in weight (g.)	Average growth per week (g.)
1	♂	0.32	28	66	+16.5
3	♂	0.32	28	60	+15.0
5	♂	0.16	28	67	+16.7
6	♂	0.16	28	65	+16.2
10	♂	0.08	28	40	+10.0
11	♀	0.08	24	25	+ 7.1
12	♀	0.08	28	28	+ 7.0

All the rats showed good growth after receiving the doses of halibut-liver oil. Most of the animals showed xerophthalmia at the time of vitamin-A depletion; this was completely cured in all animals after the administration of this oil. It is thus clear that a daily dose of 0.08 mg. of this sample of halibut-liver oil was quite sufficient for the normal vitamin-A requirements of the rat.

Conclusions

The biological results are in good agreement with the colorimetric tests. An average sample of good cod-liver oil which shows 10 blue units in 10 per cent dilution induces normal growth by a dose of 2 to 4 mg. per day. This halibut-liver oil showed 237 blue units in 10 per cent dilution and was about 24 times richer in vitamin A than an average cod-liver oil. Its rat dose should be $\frac{1}{24}$ th of 2 mg., i.e., 0.08 mg. This oil is found to be quite active in that dose. There is therefore no disagreement in the results of colorimetric and biological tests.

VALUES OF CONSTANTS IN THE ANALYSIS OF *GHI* FOR DETECTION OF ADULTERATION

By B. B. BRAHMACHARI, D.P.H.

Director of Public Health Laboratory, Bengal

EIGHT hundred samples of *ghi*, labelled as buffalo *ghi*, were received and analysed by us under the Bengal Food Adulteration Act from January 1933 to June 1934. Under the Act, buffalo *ghi* is to be pronounced as not genuine if the Reichert-Wollny value falls below 30, the saponification value falls below 222 and the refraction reading at 40°C., Ziess' scale, is outside the range 40–42.5.

In 355 of these samples, the Reichert-Wollny value was 30 and over, and so they were declared as genuine. In the other 445 samples, it was below 30; so, according to the Act, they had to be pronounced as adulterated.

One hundred of these samples had the Reichert-Wollny value at 18 or less, and were, therefore, frankly adulterated. As to the remaining 345, we know that for every 3.3 per cent of adulteration the value of this constant of a *ghi* with the value of 30 falls by 1. But, as I have shown in my paper on 'Constants of buffalo *ghi*' (1932), the analysis of 50 samples

(Continued from previous column)

The samples of halibut-liver oil which we have had occasion to examine were all about 25 times richer than standard cod-liver oil (giving 10.0 blue units in 10 per cent solution). In some instances the vendors claimed that they were 50 to 100 times richer than cod-liver oil. Therefore it is not surprising that a dose one-fiftieth or one-hundredth of a cod-liver oil dose produced no results.

At the same time it may be pointed out that a child that is weak and refuses to grow would not, in 90 per cent of cases, be suffering from a mere deficiency of vitamin A or vitamin D, and the vitamin potency of fish-liver oils cannot be judged on the basis of these clinical observations alone.

I wish to express my thanks to Professor H. E. C. Wilson for his kind interest in this work and to the Director, All-India Institute of Hygiene and Public Health, for permission to publish this note.

of *ghi* prepared by ourselves from genuine buffalo milk showed these constants to have values ranging as below:—

Reichert-Wollny value	.. 20.9–38.5
Saponification value	.. 213.6–237.5
Refraction reading at 40°C.,	
Ziess' scale 39.0–44.5

Can we, in face of this finding of our own, condemn, without further proof, all these 345 samples as adulterated, simply because the Reichert-Wollny value was below 30 and the other constants departed from their standard values correspondingly? The fifty samples of our genuine buffalo *ghi* were each from a single animal, but the market *ghis* are blends of products from several animals; so it was believed that the variation in the values observed by us in the products of individual animals would give place in the blended commodity of the market to the uniformity of the official standards. But the Reichert-Wollny value of the 355 samples declared under the Act as genuine were not concentrated at or even about 30, but ranged from 30 to 41. Can we presume that, in the genuine buffalo *ghi* of the market, the Reichert-Wollny value cannot go below 30 though it can go above that value up to 41?

As yet no adulterant or method of sophistication has been introduced into this country which would keep up the Reichert-Wollny value of the adulterated *ghi* at 30 and over; so the

deviation of the values from 30 and so form a mathematical series which can be represented by the graph of the equation:—

$$y=f(x)$$

x being deviation from the magnitude 30 and y , the frequency, i.e., number of samples of the deviation x . Before working out the values of $f(x)$, we should remember that the variates in question, i.e., the Reichert-Wollny values, are not integral but graduated, each value of the series stands for a class of values, for example, the magnitude 30 is a class with 30 as its class value and includes all values between 29 and 31. It is quite likely that some of the values at either limit of the class might be counted with those of neighbouring classes. To eliminate this error, we take for the frequency of these magnitudes the moving averages of frequencies of three magnitudes, viz, the average of each magnitude in question and of the one on either side of it. The differences between the corrected and the observed magnitudes are, however, of not much significance. The standard deviation of the series is found to be 3.5 and, so, the modulus, 4.9. We find that the frequencies are reproduced practically exactly by the equation

$$y=y_0e^{-\left(\frac{x}{4.9}\right)^2}$$

as will be evident from column 5 of table I below:—

TABLE I

Frequency of 355 samples of genuine buffalo ghi of the market with Reichert-Wollny values at 30 and higher for each of the values

Magnitude (Reichert-Wollny value)	Frequency observed (number of samples)	Frequency as corrected by method of moving averages	Frequency according to the equation $-\left(\frac{x}{4.9}\right)^2$ $y=y_0e$	Difference between columns 3 and 4
1	2	3	4	5
30	80	73	73	nil
31	67	69	69	nil
32	62	59	59	nil
33	47	47	49	2
34	31	36	37	1
35	29	25	25	nil
36	14	18	18	nil
37	11	11	11	nil
38	8	7	7	nil
39	3	4	4	nil
40	2	2	2	nil
41	1	1	1	nil

355 samples of higher values which were declared as genuine under the Act were in all probability not adulterated. An inspection of the figures for the number of samples of these different Reichert-Wollny values strongly suggests that they are a function of the

The corrected observed frequencies of all the values were the same as those derived from the equation except those of 33 and 34; the corrected observed frequencies of these values were 47 and 36, respectively, but the calculated frequencies were 49 and 37; the differences, however,

are too small to be of significance. Therefore

$$y = 73e^{-\left(\frac{x}{4.9}\right)^2}$$

is the equation for number of samples, y , out of the 355 genuine buffalo *ghis* of the market for every deviation x from the mode 30. But the equation is of a normal curve, as will be evident from it, the frequency cannot vanish on the negative side; on the contrary if we analyse n genuine buffalo *ghis* from the market and find N of them to have the Reichert-Wollny value of 30, then, provided, of-course, that those genuine *ghis* which had lower values have not been sorted out and excluded from the market, and provided also that the number n is sufficiently large, there must be $\frac{n-N}{2}$ samples with values ranging from

31 to 41 and also $\frac{n-N}{2}$ samples with values ranging from 29 to 19 and, for the same deviation from the value 30 on either side of it, there will be the same number of samples. The value of the ordinate of the graph representing the frequency of the magnitude for each deviation on either side will be :—

For deviation	0	1
	1	0.961
	2	0.850
	3	0.702
	4	0.534
	5	0.325
	6	0.243
	7	0.146
	8	0.081
	9	0.041
	10	0.019

The following chart compares the curve of corrected observed frequencies of the 700 samples of buffalo *ghi* from the market found on analysis to have Reichert-Wollny values from 41 to 19, with those for the same number of genuine buffalo *ghis* from the market according to the equation

$$y = 73e^{-\left(\frac{x}{4.9}\right)^2}$$

From it we see that while the curve of the observed frequencies of the values 30 to 41 is the same as the graph of the equation, the curve of the lower values is also continuous with it and has the same shape but keeps to a higher level for all the values, the departure increasing rapidly as the value decreases. Now while the samples of the higher Reichert-Wollny values are, under the existing circumstances, necessarily genuine, those of the lower values may be genuine or may be adulterated, their values having been reduced to the lower level by the adulteration. We should also remember that, thanks to the public analysts condemning all samples with the lower values

as adulterated, some of the big merchants are keeping chemists and refusing to accept any *ghi* of a lower value; when such rejection of buffalo *ghis* of the lower values by the merchants will be universal, the samples of all such

values received by the public analysts will of course be all of adulterated *ghis*, but then their curve will also cease to conform to that of the higher values. As it is, the frankly adulterated one hundred samples with Reichert-Wollny values lower than 19 do not fall into any mathematical series, their frequencies are as follows :—

Reichert-Wollny value	Frequencies (i.e., number of samples)
18	7
17	5
16	3
15	7
14	10
13	8
12	9
11	7
10	8
9	1
8	1
7	3
6	10
5	0
4	2
3	2
2	2
1	4
less than 1	11

In the case of the 700 market samples of the values 41 to 19 under discussion, the departure of the curve of the values 29 to 19 from that of the higher values is not so marked; therefore the genuine samples of the market *ghis* of these lower values must have been fairly

represented in it. The following table of frequency of the lower values correspond to table I for the higher values :—

All samples of class II should always be examined for other characters and direct detection of the adulterants, viz, unsaponifiable

TABLE II

Frequency of 345 samples of buffalo ghi of the market with Reichert-Wollny values of 29 to 19 for each of the values

Magnitude (Reichert-Wollny value)	Frequency observed (number of samples)	Frequency as corrected by method of moving average	Frequency according to the equation $y = y_0 e^{-\left(\frac{x}{4.9}\right)^2}$	Difference between columns 3 and 4
1	2	3	4	5
29	71	73	69	4
28	69	66	59	7
27	57	56	49	7
26	41	43	37	6
25	32	33	25	8
24	25	23	18	5
23	12	17	11	6
22	13	11	7	4
21	9	10	4	6
20	9	8	2	6
19	7	8	1	7
Total ..	345	348	282	66

So while 348 samples had values from 29 to 19 including 3 which were counted with the samples of the value 18 in the uncorrected frequency, only 66 of them were certainly adulterated; a glance at column 5 also shows that the probability of a sample being adulterated increases rapidly with the fall of the value. In any case, it follows from the above that *no buffalo ghi should be declared as adulterated simply because of its Reichert-*

matter, vegetable fats and hydrogenated oil and animal fats other than milk fat, before giving an opinion on them one way or the other. The remark applies equally to samples of these values even when labelled 'mixed cow ghi' and 'buffalo ghi or cow ghi'. The classification of the ghi under these three designations is futile for the purpose of the Act; we have no test as yet by which we can tell buffalo ghi from cow ghi and any manufacturer or merchant may

TABLE III

Class	Reichert-Wollny value	Saponification value	Iodine value	Refraction reading at 40°C.	Genuineness
I	41 to 30	238.1 to 225.3	22.1 to 32.3	39.1 to 42.1	Genuine
II	29 to 19	224.1 to 212.4	33.2 to 42.5	42.4 to 45.2	Doubtful
III	18 and less	211.0 and less	43.5 and over	45.5 and over	Adulterated

Wollny value being less than 30, if that value is still between 29 and 19 and the departure of its saponification values, iodine value and refraction reading correspond to the lower Reichert-Wollny value. For Reichert-Wollny value below 19 there is very little chance of a sample being genuine. So regarding genuineness on the basis of the values of their above-named constants, samples of ghi fall into three classes shown in table III.

very well adulterate buffalo ghi to the extent of 20 per cent or over, and yet it will pass as genuine cow ghi, if we satisfy ourselves simply with the Reichert-Wollny value, the saponification value and refraction reading, and even with the iodine value.

A SIMPLE METHOD OF BUG DESTRUCTION

By J. N. PACHECO, M.R.C.S., L.R.C.P., I.M.D.
Deputy Superintendent, Ranchi European Mental Hospital

ONE of the minor problems of hospital administration in the East is the elimination of bugs from the wards. The reputation of a hospital, especially among the general public, is sometimes gauged by the presence or absence of this pest. There are innumerable ways of destroying the bed-bug, but it is doubtful if the time and money spent on disinfection is commensurate with the results, for no sooner are we satisfied that disinfection has been thorough and complete than the bug makes its reappearance. The cause of this is that none of the modes generally employed—be the disinfecting agent chemical, liquid, gaseous or thermal—brings about total and complete destruction, and, what is more important, acts as a barrier to future invasion.

The following notes are published with a view to showing the success that has been achieved at the Ranchi European Mental Hospital, and with the hope that the method may be of some use to those hospitals that find bug disinfection a problem.

Until recently there was hardly a bed in this hospital that did not at certain seasons harbour bugs, and that in spite of the fact that every bed, mattress and pillow had been disinfected once a month.

The old method of disinfection was as follows :—

Once a month all the iron beds with their mosquito-pole fittings were immersed for ten minutes in a large iron tank containing boiling water and after drying in the sun they were wiped down, reassembled and put back in the wards. All mattresses, pillows and nets were subjected to the effects of steam for half an hour each, in a Thresh's disinfector, working at 5 to 10 lbs. pressure. This method entailed not only a recurring expenditure on coal and fuel for the tanks and the boiler, but a party of coolies had to be employed in moving the beds and mattresses from the dormitories which are mostly on the upper floor. In addition to the disorganization of the ward for the better part of the day, beds, poles, or fittings were often damaged in transit. The end-result was that bugs made their reappearance by the end of the month.

Another mode of attack was tried by heating the beds with an open flame from a blow lamp but this was equally ineffective. Fumigation was not attempted for reasons of expense and the attendant dangers. It was strange that dormitories on the first floor were more heavily infested than those on the ground floor. The engineers thought that bugs were breeding in the cracks and crevices in the walls, doors or

floor, or that they dropped from the roof and the electric wire casings. The latter were opened and examined and all crevices well filled up with cement. No appreciable improvement followed.

In August 1930, our Inspector-General of Civil Hospitals, the late Colonel W. Houston, I.M.S., came to our rescue during an inspection, with the suggestion that we should wipe all beds down with ordinary coconut oil. His experience of numerous methods of disinfection whilst Port Health Officer of Bombay taught him that coconut oil is a poison to the bed-bug and that the application of coconut oil is the only effective and economical way of eradicating bugs completely. Disinfection of all wards was then carried out, according to his instructions, by Dr. S. A. Hasib.

Bug census.—Kraepelin Ward was chosen for taking a census of bugs, as this ward was mostly heavily infected.

Four beds were marked out in this ward and a bug census done on them on 6th August, 1930. The results were as follows :—

Bed No. I	1,177 bugs
" " II	1,253 "
" " III	933 "
" " IV	879 "

Thresh's disinfector.—The efficiency of the disinfector was tested by putting a dozen bugs in four small cloth bags and then placing them inside the mattresses and disinfecting them. Six mattresses were disinfected at a time. The bags containing the bugs were placed in mattresses at four different levels, the top, bottom and the middle ones. After half an hour's exposure to steam the mattresses were taken out and the bags examined. The bugs in all four bags were found dead.

Procedure

(1) All the mattresses and pillows were disinfected in the Thresh's disinfector for half an hour.

(2) All cots and mosquito poles were immersed in boiling water for ten minutes each.

(3) The cots and poles were then painted with pure coconut oil and put back in the wards.

All other wards were similarly disinfected on the following days.

On 13th August a bug census, of the same four beds that were examined the previous week, was done again and the results were now as follows :—

Bed No. I	178 bugs
" " II	54 "
" " III	126 "
" " IV	34 "

Disinfection of all cots, mattresses, etc., was again repeated as in the previous week. In addition the corners and the junctions between

the walls and the floor were all painted with coconut oil. All doors, windows, corners and crevices were sprayed with a solution of kerosene oil emulsion prepared as follows:—

Half a pound of soap was mixed with a gallon of cold water and then boiled; the boiling water was then slowly poured into two gallons of kerosene oil and constantly stirred. It formed into an emulsion which was mixed with fifty gallons of water.

On 20th August, the bug census on the same four beds was as follows:—

Bed No. I	10 bugs
" " II	4 "
" " III	5 "
" " IV	8 "

Disinfection was again carried out as in the previous two weeks.

The above procedure has been followed in all wards till all the bugs have been completely destroyed. At present the disinfecting process has been reduced to merely wiping down all cots once a week with a rag dipped in coconut oil. The cost is exceedingly small, the procedure simple and all the bother of removing beds for boiling and mattresses for steaming has been eliminated. The result is that bugs are now entirely absent.

I am grateful to the medical superintendent for permission to publish this paper, as well to Dr. S. A. Hasib, M.B., for his notes on the experiments carried out by him.

A Mirror of Hospital Practice

FIVE CASES OF RHINOSPORIDIOSIS, FOUR IN FEMALES

By F. R. W. K. ALLEN, M.A., M.D. (Dub.)

MAJOR, I.M.S.

Civil Surgeon, Raipur

REPORTS of rhinosporidiosis in females are rare. The five cases recorded here may therefore be of interest. No other cases or any other kind of nasal growth or polypi have been seen at the Main Hospital, Raipur, during the last eighteen months.

Case 1.—A married Hindu female labourer, aged 30, of Dhore village, Bhilai Thana, Drug district, Central Provinces. She came complaining that three months previously a slight swelling occurred in her right nostril and this had gradually grown to its present size. On examination it was seen that a red mass of granulation tissue, which bled freely when touched with a probe, filled the right nostril. The mass was the size of a ground-nut and grew from a pedicle attached to the anterior end of the inferior turbinal. The tumour was removed on the 5th January, 1934, and was sent for examination to the Haffkine Institute, Bombay, which reported that the condition was rhinosporidiosis.

Case 2.—A married Hindu female of the Dhobi caste, aged 25. She had never left her village of Satbhawa in Simga Thana, Raipur district, Central Provinces, until the beginning of September 1934. She complained that eight months previously she noticed a 'pimple' in her right nostril and that since then it had gradually grown to its present size. On examination it was seen that a red mass of granulation tissue, which bled slightly when touched with a probe, filled the right nostril. The mass was the size of a ground-nut and grew from a pedicle attached to the anterior end of the nasal floor. She stated that none of her relatives suffered from similar growths. The tumour was removed on the 27th September, 1934. A portion examined locally under the microscope showed typical round cystic bodies full of spores. A portion of the growth was sent to the pathologist, Robertson Medical School, Nagpur, who confirmed the diagnosis of rhinosporidiosis.

Case 3.—A Hindu female child, 8 years old, daughter of a weaver of Maldi village, Raipur district. She

was brought to the Main Hospital, Raipur, for a growth which protruded out of her left nostril.

Her mother stated that some time back the child commenced to suffer from occasional attacks of bleeding from the nose. About six months ago the growth was noticed. It gradually enlarged until it became the size of a large bead. It was ulcerated and foul smelling.

On the 12th November, 1934, the growth was removed by means of a snare, during my absence. It was growing from the septum. On my return I was shown the tumour which was about the size of a ground-nut. It was a typical red cauliflower-like growth springing from a fairly broad pedicle. Local examination under the microscope showed *Rhinosporidium* and a portion of the tumour, sent to the pathologist, Nagpur, for preparation of sections, was reported upon as a rhinosporidial growth.

Case 4.—A Hindu female agriculturist, about 50 years of age, of Phapuadi, Raipur, came to the Main Hospital, Raipur, on the 27th December, 1934, for a large red cauliflower-like mass which protruded from her right nostril. Six months ago she noticed that the inside of her right nostril was very itchy and since then the tumour grew until it completely blocked the nostril. None of her friends or relations suffer from a similar complaint. The nasal secretion was examined and typical rhinosporidium seen. At the time I was unable to examine the case more fully and she was told to return next day for operation but failed to put in an appearance.

Case 5.—A male Brahmin malguzar and cultivator, 22 years of age, of Rajim in Raipur district, came on the 23rd December, 1934, complaining of a large red cauliflower-like growth protruding from his right nostril. The nasal discharge was examined and typical rhinosporidium seen. He stated that eight years previously he suffered greatly from itching in his right nostril. Shortly afterwards the nostril became blocked and caused difficulty in breathing. Then he noticed the tumour which grew slowly and at times bled freely. In 1930 it was removed at the Main Hospital, Raipur, but recurred after a year. It was arranged that he should come for removal of the growth next day, but he arrived so late that the operation was postponed and he failed to put in an appearance again.

Such cases are usually diagnosed as nasal polypi but they are obviously not ordinary polypi. I am under the impression that rhinosporidial infections are not uncommon in

the rice-growing tracts of the Raipur and Drug districts. It is possible that the spores are inhaled when rice is being husked and find a suitable habitat in some abrasion of the nasal mucous membrane from whence the tumour grows. Unless the whole tumour and pedicle is most carefully removed it is almost certain to recur for spores can be found in the pedicles.

A CASE OF RETAINED GANGRENOUS PLACENTA

By JAGADISH CHANDRA DUTTA, L.M.F.

Rajah Alli Tea Estate, Hoogrijan P. O., Assam

I was called in recently to see a case of retained placenta in a Hindu multipara, aged about 22 years. She had been delivered of a male child three days ago but the placenta had not been expelled. The patient and her relatives thought that it would come out spontaneously. When they saw that it was not expelled they called a *dai*, who along with others roughly handled her without any antiseptic precaution and tried their utmost to extract the placenta but without success. When I was called in there was a bad odour coming from the vagina. On examining the case I found that the placenta was in a gangrenous state and I therefore removed it by hand, piece by piece. The vaginal mucous membrane was very red, inflamed and tender to touch. I thoroughly douched out the vagina and the uterus with Monsol lotion after removing the placenta. On the next day I went to see the case prepared to douche out the vagina and uterus again but the patient did not allow me, saying that she was feeling quite fit and well. There was no temperature. I gave the patient ergot mixture with brandy. She made an uneventful recovery.

The peculiarity of the case was that there were no signs of sepsis, although the placenta was in a gangrenous condition and the uterus had been roughly handled by the *dai* and others without any antiseptic precautions.

I am indebted to my medical officer, Lieutenant-Colonel F. J. Palmer, for his kind permission to publish this note.

A CASE OF NASAL MYIASIS

By A. K. GHOSE, L.M.F., L.T.M.

Ambari Tea Estate, Carron P. O. (Jalpaiguri)

On the 5th August, 1934, a coolie, aged about 55 years, came to the dispensary complaining of a very uneasy sensation in his nasal cavity.

On naked-eye inspection nothing could be found out, so he was sent away without obtaining any relief. Next day he again came and complained that he felt as if something had entered his nostrils. On further enquiry he told me that about a week ago, while he was working in the garden, a fly entered his nasal cavity and after a short time it came out in the living condition. He did not report this matter to me previously, as he had no idea that his present trouble had any relation with the entrance of the fly. Again I examined his nose but failed to detect anything. Thinking however that it might be a case of nasal myiasis, I douched out both nasal cavities with a weak lotion of spiritus chloroformi, as suggested by Dr. Strickland. Forty-five living maggots (the species of the larvæ could not be identified) came out of his nasal cavity. The patient felt immediate relief from his complaint.

It is very interesting to note how a fly could lay its eggs in that unfavourable site within such a short time.

A CASE OF GYNÆCOMASTIA

By A. C. DEY, L.M.F. (Cal.)

Senior Resident Medical Officer and Pathologist, Astanga Aurved Medical College Hospital, Calcutta

M. C., Hindu male, aged 24 years, a clerk by occupation, was admitted in the Astanga Aurved Hospital for operation for gynæcomastia (right side) on 19th September, 1934.

Previous history.—The patient said that the malady commenced about three years ago. Both the sides were originally of equal size and shape until the right side began gradually increasing in size. There was no discomfort although the patient felt uneasy in his mind owing to his appearance (*see figure*).

Reproductive system.—The testes were of equal size and could be felt in the scrotum. The penis was of normal size. The voice and the growth of hair in the

pubis and face was like that of a young healthy male adult. The general appearance of the patient was healthy.

The tumour.—Circumference—16 inches; lateral border—1 inch anterior to the mid-axillary line; upper border—at the third right intercostal space; lower border—at the seventh right intercostal space. The feel of the organ was soft and nodular. The nipple was of equal size with that of the healthy side. No lactation was present.

The operation was performed on 23rd September by Dr. S. C. Das, M.B., under chloroform anaesthesia. The weight of the gland substance was 13 ounces.

Special points to note in this case are (1) unilateral, (2) the development was more than an ordinary gynæcomastia, (3) the presence of well-marked lobules, (4) a well-formed scrotum and penis, (5) the testes on both sides equal with normal epididymis.

The case was admitted under Dr. Ghosh, and I am grateful to him for permission to publish the notes of this case.

A CASE OF GYNÆCOMASTIA

By S. RAMDAS, L.M.S., L.C.P.S., L.R.C.P., M.R.C.S.

Assistant Surgeon, L. F. Hospital, Bobbili, Vizagapatam District

S. N., a male, aged 25 years, was admitted here on the 7th September, 1934, on account of an enlarged left breast.

On examination the breast was as big as that of a healthy multiparous woman with a distinct areola and a fairly big nipple. The gland felt quite uniform to

palpation. There was no inflammation of the gland nor any other pathological condition in and around the breast nor on the skin covering the organ. There was no congenital malformation in any part of the body. As is seen in the text-figure it is evident that the sexual organs are not diminutive but on the other hand appear well developed.

The man is married and, I learn, his wife is pregnant. No peculiar circumstances were found to excite the

growth of this breast. The right breast is quite normal, the nipple is small and pointed and the areola is surrounded by sparse hairs. All the secondary characteristics of a male are evident in the patient. His voice is masculine and there is nothing in his behaviour to suggest that he is of a feminine disposition.

I removed the gland under chloroform by an incision on the line of the lower border of the pectoralis major taking care to preserve the nipple and areola on the same level as the right. The wound healed by first intention and the scar is scarcely visible.

A CASE OF A FIBROMYOMA OF THE VAGINAL WALL?

By S. R. GORE, L.M. & S.

Co-operative Hospital, Hubli

NEELAVA IRBASAPPA, aged 40, was admitted into the Co-operative Hospital, Hubli, on 18th August, 1934, for retention of urine. The retention was of four days' duration, and effort to relieve the bladder was made by a medical man about twelve miles from Hubli, who being unable to draw urine advised the patient to seek treatment at the Co-operative Hospital. In a note he sent with the patient he writes 'I tried to pass catheter but on passing only bloody serous discharge came out'.

On examination it was found that the anterior vaginal wall was protruding outside the vulva, it was very tense, fluctuation could be elicited, and a bloody foul-smelling discharge was oozing slightly from the space between this protruding tumour and the symphysis pubis. The urethra was pressed against the bone and could be found only after a careful search; when this was catheterized a large quantity of urine came out. Evidently the urethra was not found by the medical practitioner who referred the case to us, and it is evident he pricked the vaginal wall high up between the protruding mass and the bladder. The foul-smelling discharge that escaped came from this part. The mass that was protruding was taken by the writer of the article to be the fundus uteri in extreme anteversion with the cervix high up in the posterior fornix. It was not possible to locate the position of the cervix as no speculum could be passed and the finger could not feel it. The abdomen when palpated showed that the whole of the pelvis was occupied by a tumour, which when pressed gave a fluctuating sense to the finger on the protruding vaginal wall.

A provisional diagnosis of an impacted cyst pressing the uterus down in an anteverted position was made and laparotomy was undertaken under general anaesthesia. The patient's general condition was poor.

On opening the abdomen the uterus and the bladder were seen pushed up into the abdomen by a tumour occupying the whole of the pelvis. The size of the uterus was normal and it was completely unconnected with the tumour, which was subserous. It was hard and seemed to be so fixed that an attempt to remove it by the abdominal route, in the presence of the foul discharge from the vagina and the low condition of the patient, was considered inadvisable; the abdomen was therefore closed. An incision was made in the protruding vaginal wall to allow the fluid collected between it and the tumour to escape. The finger introduced through this incision could not make any progress in separating the tumour from the surrounding tissues. It was therefore decided to try to remove the tumour by the vaginal route at another operation if the patient responded well after the relief of the tension and by being catheterized regularly.

On the next day it was found that the tumour was protruding more from the vagina and the woman was getting pains at intervals resembling labour pains. She was operated on on the 21st and on the 24th instant in the night the whole of the tumour was expelled, a very small pedicle of connective tissue

being its only attachment. This was ligated with catgut and the tumour removed.

The patient made an uninterrupted recovery.

The dimensions of the tumour are eight by four and a half inches at the broadest upper end which was felt to be filling up the whole of the pelvis from the abdominal aspect. The weight of the tumour is two pounds.

On inspection of the tumour the cause of my being unable to separate it was revealed. I had cut into the tumour itself and was trying to separate it from inside which was obviously impossible. The vaginal wall was practically fused with the tumour where it was protruding but the pressure of the pelvic muscles threw the whole tumour out, once the vaginal wall was incised.

The interesting point in the case is the demonstration of the tremendous power which the muscles of the floor of the pelvis possess and one can imagine the aid they must give the uterine muscle in expelling the foetus in parturition. I am sure that even if I had succeeded in separating the tumour with my finger I would have found it practically impossible to deliver it with the hand as it was very broad at its upper pole.

I call it a myoma of the vaginal wall because it was completely unconnected with the uterus and was so much in connection with the anterior wall of the vagina.

The duration of the tumour cannot be definitely stated as the history given by the patient is quite unreliable. Her attention was drawn to it only after the retention of urine and then she thought she felt something heavy in the abdomen for four months previously.

I am citing this case because the power of the pelvic muscles is exhibited so plainly.

ACUTE EMPYEMA IN CHILDHOOD

By P. N. RAY, B.A., M.B., F.R.C.S. (Eng.)

Honorary Junior Visiting Surgeon, Medical College Hospitals, Calcutta

EMPYEMA is a serious complication of lobar and broncho-pneumonia, especially in children. Nearly 75 per cent of all empyemas occur under the age of ten years. Consequently the importance of early and adequate surgical treatment is evident; but, unfortunately, early diagnosis of empyema is not always easy. If the temperature does not subside after an attack of pneumonia or if the attack is unduly prolonged, empyema must always be considered first as the underlying cause of mischief. The following case presents many unusual features and seems to be worthy of record :—

R., a male child, aged 4 years and 6 months, was admitted into the children's ward of the Medical College Hospitals for continued pyrexia and cough of one week's duration.

On examination.—The patient looked very ill. Temperature, 101.5°F.; pulse rate 120 to 140; tongue, furred; tonsils, enlarged; pharynx, congested. Cervical and submaxillary lymphatic glands were enlarged. Bronchial râles and rhonchi were present on both sides, the base of the left lung was also dull on percussion. The child complained of abdominal pain. Spleen, palpable below the costal margin. Liver, slightly enlarged. Diarrhoea was present from the beginning.

History of past illness.—The patient suffered from measles at the age of two years and from tonsillitis and malaria when he was three years old.

Family history.—A cousin, living in the same house, died of pulmonary tuberculosis.

Examination of blood

	On admission	Two weeks later
Hb.	55 per cent	..
R.B.C.	3,100,000 per c.mm.	..
W.B.C.	16,000 per c.mm.	14,500 per c.mm.
Polynuclears..	82 per cent	88 per cent
Lymphocytes	18 "	12 "
Large mono.	0 "	0 "
Eosinophils	0 "	0 "
Parasites	None seen	None seen.
Widal	Negative	Negative.
Culture	No growth	No growth.

Examination of sputum.—Nothing abnormal was found after repeated examinations.

Examination of urine.—Chemically this was normal but there were some pus cells, phosphates and urates microscopically.

Examination of faeces.—Culture reports.

1	2	3	4
<i>B. coli</i> <i>Enterococci</i> <i>B. faecialis-</i> <i>caligenes.</i>	<i>B. coli</i> <i>Enterococci</i>	<i>B. coli</i> <i>Enterococci</i>	<i>B. coli</i> <i>Enterococci</i> <i>B. aerogenes-</i> <i>lactis.</i>

Progress of the case.—During a period of 25 days, the pyrexia continued as before. The daily range of temperature varied between 99° to 100°F. and 102° to 103°F. The continued dullness of the left lung on percussion was the most noteworthy feature. Breath sounds and vocal fremitus showed hardly any diminution at all. Bronchial breathing could be heard. The spleen was enlarged. The general condition of the patient was gradually becoming very feeble. The results of the laboratory examinations are noted above.

Skiaigraphy of the chest.—A homogeneous opacity was seen on the left side, but the heart was not pushed out (see figure).

Paracentesis thoracis.—After repeated punctures, pus was localized but was withdrawn with difficulty owing to its viscosity. A pure culture of pneumococcus was subsequently obtained from the specimen.

Operative treatment.—Under combined ether and local novocaine anaesthesia one inch of the eighth rib was resected just in front of the mid-axillary line and about six ounces of creamy pus were let out and the cavity was drained in the usual way. The patient made an uneventful recovery and the wound was completely healed before he was discharged from the hospital.

Commentary

In empyema, generally there is a diminution of both the breath sound and the vocal fremitus,

but in case of children it may not be so, whence arises the difficulty of diagnosis. In a typical case, the general features of pneumonia may be present, but locally the cardinal signs consist of impairment of respiratory movements, displacement of thoracic viscera, dullness on percussion and absence of breath sounds. Frequently, however, as in the case described above, the clinical picture is that of empyema, but the physical signs may not be corroborative. On radiological examination of the chest, a homogeneous opacity was seen on the left side, but the heart was not pushed out. The differential diagnosis lay between massive pneumonia and pleural effusion. After repeated needling, pus was localized but withdrawn with difficulty, owing to its thickness. On culture of pus, a pure growth of pneumococcus was obtained. Drainage was established after rib resection and six ounces of pus were let out. The absence of any cardiac displacement was rather surprising. It was a rare instance of localized empyema complicating an unresolved pneumonia. In children, suppuration within the pleural cavity is frequently localized and encysted, particularly in the middle third of the thorax.

The diagnosis of crypto-empyema is admittedly difficult and an exploratory operation may be called for. A skiagram is useful, but cannot always be relied upon. In case of interlobar or basal encysted empyema, radiograms, taken in the direct lateral position, are

extremely useful in localization. A crypto-empyema may underlie the so-called 'unresolved pneumonia'. Before undertaking any exploratory operation it is, however, imperative to exclude the possibility of pulmonary tuberculosis or gangrene of the lung, by careful and repeated examinations of the sputum. It is scarcely necessary to add that repeated needling is not entirely devoid of danger. The area of the lung may not be closed by adhesions and a generalized empyema may be produced. Haemorrhage may also be serious. It is well to remember that negative results after repeated punctures may be due to blockage and insufficient length or calibre of the needle. The needle is readily blocked by thick pus or masses of fibrin. It may also push the thickened pleura in front of it. Repeated punctures are best made under local anaesthesia. With regard to the question, when to drain, two general principles may be accepted: (1) If there is no pneumonia (meta-pneumonic empyema), operation is indicated as soon as the diagnosis is made. Nothing is gained by waiting. (2) If pneumonia is present (syn-pneumonic empyema), especially streptococcal, the rate of mortality is appallingly high. Aspiration, repeated if necessary, is the method of choice till the pneumonia is resolved. The persistence of a sinus after open drainage, a dreaded sequela, is usually either due to non-expansion of the lung or the superposition of secondary infection. Hence the best safeguards consist firstly of early and adequate drainage and secondly of observance of strict asepsis in dressing.

Summary

(1) The difficulties of diagnosis of empyema in childhood are discussed. Suppuration within the pleural cavity is frequently localized and encysted, particularly in the middle third of the thorax.

(2) An interesting case of empyema, complicating unresolved pneumonia, is described. On skiagraphy of the chest, a homogeneous opacity was seen on the left side but the heart was not pushed out. On rib resection, six ounces of pus were let out.

(3) If there is no pneumonia (meta-pneumonic empyema), operation is indicated as soon as the diagnosis is made. Nothing is gained by waiting.

(4) If pneumonia is present (syn-pneumonic empyema), aspiration, repeated if necessary, is the method of choice, until the pneumonia is resolved.

(5) The formation of a sinus after open drainage is best avoided by early and adequate drainage and avoidance of secondary infection.

I wish to acknowledge my indebtedness to Mr. L. M. Banerji and Lieut.-Col. J. C. De, I.M.S., for their valuable help and advice.

A PECULIAR CASE OF VESICO-VAGINAL FISTULA

By M. L. TRESTON, F.R.C.S., F.C.O.G.

LIEUTENANT-COLONEL, I.M.S.

Medical Superintendent, Dufferin Hospital, Rangoon

SOME two months ago a young Burmese girl, aged 20, was delivered of her first baby. Living many miles from medical attendance, the patient had to depend on the local 'Sarah Gamp' with the result that the baby was still-born, and the mother came to Rangoon, two months later, with a vesico-vaginal fistula.

The fistula was to the left, tucked under the left pubic ramus, about midway between the urethra and the base of the bladder, and was already extensively fibrosed. There was a linear scar from the posterior margin of the assumed vaginal orifice, extending to the rectum. This was soundly healed. The vagina was only one and a half inches long and there was no cervix uteri to be seen or felt. On rectal examination, the outlines of a normal uterus could be made out. At operation the apparent posterior vaginal wall was stripped completely up, and some two and a half inches from the vaginal orifice the cervix uteri was discovered. The stripped mucous membrane was cut short and partly attached to the cervix and partly to the posterior aspect of the fistula after it had been repaired. The uterine cavity was two and a half inches and there was a slight brownish discharge on passing the sound. The fistula healed by first intention, the uterus is normal and the vagina seems normal, except that it is somewhat short, two and three-quarter inches. Apparently the anterior vaginal wall and a portion of the bladder wall were torn, and the former was sutured to the bruised posterior vaginal wall, a few more stitches in the torn perineum completing the operation. This shut the uterus off completely, and it would be interesting to know what happened as regards the lochia. There was a history of fever following confinement, but it was not of a very marked type and the patient, on the whole, was fairly fit on admission to hospital.

A CASE OF BINOCULAR SUBLUXATION OF THE LENS IN A CHILD

By HANS RAJ, M.B., B.S., L.O.

Kaisar Bagh, Lucknow

M. L., a male child, eleven years of age, brought in on the 1st August, 1934, complaining of defective vision and squint.

Vision—right eye—wearing +3.0 spherical = 6/36; left eye—wearing -7.0 = 6/24. Left eye—divergent. Cornea—clear in both eyes. Iris tremulous in both eyes, the right much more than the left. Anterior chamber—right eye outer portion slightly shallower than the rest. Slight signs of an old iritis in both eyes. Pupil—in both eyes active. In right eye outer portion showed a greyish convex crescent, looking like a dislocated lens. Left eye—normal.

Under homatropin :—

Right eye—lens was markedly dislocated, lying behind the outer portion of the iris. It was very globular, almost spherical and tags of iris tissue were adherent to its margins on all sides. The lens capsule was greyish white, the lens cortex looked translucent and the lens as a whole had an opalescent appearance. The fundus was highly hypermetropic.

Left eye—the iris was slightly tremulous. The lens was slightly dislocated outwards, the extent of dislocation being such that the portion of pupil occupied by the lens in the right eye was equal to the portion unoccupied in the left, as illustrated.

The condition of the lens was similar to that in the right eye. There was a double fundus reflex, one portion highly hypermetropic, the other myopic. In both eyes the vitreous had large floating opacities. Several large white patches of organized white exudates were present in the left eye near the macular.

Retinoscopy :—

Right eye $\frac{+8.0}{+7.0}$ Left eye $\frac{-6.0}{-9.0}$

The vision was not improved by cylinders and it was found to be -right eye with +6.0 spherical = 6/24 & J12 and left eye with -6.0 spherical = 6/24 & J4 after the effect of the homatropin had passed off. Binocular vision was not possible.

There was a history of a fall from a roof four or five years previously, but none of any eye trouble following. An ophthalmic surgeon, who saw the child some time after, prescribed only glasses, but did not mention to the father any dislocation of the lens.

A LARGE OVARIAN CYST IN A YOUNG GIRL

By G. M. IRVINE, M.D., F.R.C.S.E.

CAPTAIN, I.M.S.

Civil Surgeon, Bassein

THE following case of a large ovarian cyst in a young girl appears to be somewhat unusual :—

M. N. Y., a young Burmese woman aged 17 years and 10 months, was admitted to hospital on 24th September, 1934, on account of a large abdominal tumour.

History.—This tumour was first noticed between one and two years previously and had subsequently increased steadily in size. She had been married for nine months. She had amenorrhœa for two months. The menses previously had been regular.

Beyond a certain amount of discomfort and distress on account of the size of the abdominal tumour she complained of no other symptoms.

Examination.—There was a large tumour about the size of a full-term pregnancy filling the whole abdomen and extending to the xiphoid cartilage. The tumour was fluctuant and its outlines were somewhat difficult to determine on palpation. It was dull all over on percussion. Pelvic examination revealed nothing.

An exploratory aspiration was carried out and a few cubic centimetres of mucinous or pseudo-mucinous fluid was withdrawn.

The patient appeared to be in excellent general health otherwise.

A diagnosis of ovarian cyst or pseudo-myxoma of the peritoneum was made.

Operation.—At operation a large left-sided ovarian cyst was found filling the whole abdomen. This was partially evacuated and removed. The uterus was found to be pregnant and a corpus luteum of pregnancy in the other ovary. The duration of the pregnancy was about two months.

The patient made an uninterrupted recovery. Though abortion was feared this did not take place and the pregnancy is pursuing a normal course.

The tumour was found to be a pseudo-mucinous cyst of the usual type. It consisted chiefly of one large cavity from which over one and a half gallons of fluid were evacuated.

Comment.—I can find no reference in the available literature to the age incidence of ovarian cysts but the occurrence of a cyst of such dimensions in a girl of 17 years and 10 months is unique in my experience. The association of pregnancy with a tumour of such size is also of interest.

A STRANGULATED HERNIA

By N. K. GUHA NIYOGI, B.Sc., M.B.

Nawabganj Charitable Dispensary, Malda

A HINDU male, aged 40, came to the hospital at 5-15 p.m. on the 30th October, 1934, with a large tense scrotal swelling the size of a small football. He had severe abdominal pain and vomiting.

On examination the swelling was found to be a strangulated inguinal hernia of the left side. There was no impulse on coughing. It was reported, on enquiry, that the hernia had come down at about 1 p.m. on the same day and that the patient, as usual, tried to reduce it but in vain.

At first I tried taxis for some time without any success. Then I gave an injection of atropine sulphate 1/50th of a grain subcutaneously at about 6-30 p.m. and ordered water to be poured over the swelling constantly. I waited for half an hour and then tried taxis for a short time again. In the meantime ice was available and it was applied over the swelling for about one hour. Taxis was again tried, when the scrotal swelling began to diminish in size and it was completely reduced with gurgling sounds. The patient felt an immediate relief and was discharged on the same night.

A CASE OF POLYCYSTIC DISEASE OF THE KIDNEYS*

By A. C. DEY, L.M.F. (Cal.)

Senior Resident Medical Officer, Astanga Ayurved Medical College Hospital, Calcutta

D. G., Hindu, male, aged 40 years, medical practitioner by profession, was admitted into the Astanga Ayurved Hospital on 9th November, 1934, for the treatment of the following complaints:—

Bilateral tumour in the lumbar regions, persistent hæmaturia, and debility.

Previous history.—The patient said that he first noticed a growth in the right lumbar region about four years back. A few months after this the left side also became enlarged. There was no pain nor any discomfort in the beginning. About six months after the appearance of the tumours one morning he noticed a few drops of blood with his urine. He did not think this of much importance but that night he had an attack of severe pain in the region of the tumours. Gradually the tumours became enlarged in size and the hæmaturia used to occur off and on with occasional rise of temperature. He was treated by a village doctor without any good effect. For the last five months the patient says that the pain on the site of both the tumours has become constant and with each act of micturition he used to notice blood.

The condition of the patient was not good. He had pyorrhœa and the tongue was coated. His pulse was somewhat rapid and there were a few râles in his lungs. Blood examination revealed marked anæmia with 1,500,000 red cells and 47,000 leucocytes per c.mm.

Palpation of kidneys.—On the right an irregular fluctuating mass occupying the whole of the right lumbar and the major part of the right hypochondriac regions could be felt. A distinct gap could also be felt between the tumour and the enlarged liver. It was extremely painful to touch.

The left kidney occupied the whole of the left lumbar and part of the left hypochondriac regions and was entirely separate from the enlarged spleen. Its surface was irregular and deep fluctuations could be felt. It was also extremely painful to touch.

Examination of the urine.—The total quantity was on an average 15 to 20 ounces in 24 hours.

Physical examination:—

Specific gravity 1034
Reaction acid
Albumin present in fair quantity
Sugar nil
Phosphates nil

Microscopical examination:—Casts—blood, hyaline and granular present.
Red blood cells—present.

A diagnosis of polycystic disease of the kidneys was made by the writer.

The patient died on the 21st November, 1934.

The two kidneys were extracted post mortem and innumerable cysts from the size of a pea to a marble were found on the surface of both. The cysts contained reddish brown fluid containing albumin, triple phosphates and fat drops.

On section very little kidney tissue could be detected. The right kidney weighed one and three-quarter pounds and the left one pound.

* Rearranged by Editor.

A CASE OF RAT-BITE FEVER

By T. R. SWARUP, F.M.S., M.B., B.S., M.R.C.P. (Lond.)
M.R.C.S. (Eng.)

Medical Officer-in-charge, General Diseases Hospital
Hardwar

PATIENT aged 35 years, Hindu male, tin-smith by trade, was admitted to the medical wards of the General Diseases Hospital, Hardwar, on 9th September, 1934, with the following complaints:—

1. Fever—thirteen days' duration.
2. Pain and swelling of the joints for ten days.
3. Rash on the front and back of chest and abdomen—ten days' duration.
4. Inflamed black patch on the front of right leg at the site of rat bite, measuring about two inches by three-quarter of an inch, of twenty days' duration.
5. General weakness and prostration.

History of present illness.—Twenty days ago, the patient was sleeping at night in his cot and was bitten by a rat on the front of right leg. The site of the bite became inflamed and cedematous. Except for this, he was well for seven days. He then developed fever accompanied with general disturbances and pain and swelling of the knee and ankle joints. After two or three days of fever, he developed a rash which still persists on the front and back of the chest and abdomen.

Physical examination.—The patient is a young man of good physique; he was slightly anæmic and looked obviously ill, even prostrated. The temperature at the time of admission was 101.4°F. and the pulse rate 110 per minute. Oedema was present over his feet. The site of the rat bite was inflamed and tender. (No ulceration nor gangrene was noticed). There was a purple scarlatiniform rash on the front and back of chest and abdomen. The spleen was enlarged. The liver was not palpable. No enlargement of the glands was noticed anywhere. The joints were not inflamed but the knee, the ankle, the wrist and elbow joints were definitely tender. Nothing abnormal was detected in the circulatory, respiratory, nervous and genito-urinary systems of the body.

Pathological examination.—The blood examined for *Spirillum minus* was found to be negative. The urine did not reveal anything abnormal.

Progress report.—On the day of admission, an intravenous injection of 0.45 gramme neosalvarsan was given with the result that the temperature came down to 97.6°F. next day and continued to remain below normal until he was discharged from the hospital, i.e., nine days after admission. During this period he felt better from day to day until all his symptoms gradually disappeared. I repeated the second injection of 0.45 gramme neosalvarsan on the eighth day. On the day following this injection, the patient felt so much better that he solicited his discharge from the hospital.

Commentary.—Rat-bite fever has been known to exist very commonly in Japan. Its rarity in India, when compared to the enormous number of rats that inhabit Indian houses, has prompted me to report this case.* Moreover

* [The acceptance or otherwise of the writer's suggestion regarding the rarity of the disease in India is dependent on one's interpretation of his qualifying phrase 'when compared to the enormous number of rats that inhabit Indian houses'. In a period of 9 years, 70 cases of rat-bite fever, all diagnosed by the finding of the causative organism, *Spirillum minus*, attended the Calcutta School of Tropical Medicine; the majority of these were treated and cured by neosalvarsan or one of the allied arsenicals.

Rarity is not however the only excuse required to justify publication of a case.—Editor, I. M. G.]

the marvellous results of neosalvarsan therapy, as evidenced in this case, are worth recording.

The incubation period in this case was seven days (the usual period being five to ten days). As the patient submitted himself to medical treatment rather earlier, relapses which are such a common feature of this type of fever did not occur.

The cutaneous rash was very characteristic of the disease; this took the form of a purple scarlatiniform exanthem on the chest and abdomen. The extreme prostration and agony of the patient together with the tender joints and enlarged spleen formed a typical picture. The site of the bite did not show any ulceration nor gangrene, apart from a slight tenderness, and the glands were not enlarged.

The striking result of neosalvarsan therapy is a point to be specially borne in mind from the point of view of treatment.

Special Article

THE NEW SYNTHETIC DRUGS*

By PROFESSOR DR. MED. DR. PHIL. W. SCHULEMANN
Elberfeld, Germany

PLASMOCHIN was discovered in 1924 in the scientific laboratories of the I. G. Farbenindustrie Aktiengesellschaft in Elberfeld. Roehl noted its action in the malaria of canaries, and Sioli that in the therapeutic malaria of general paralytics. We then proceeded to investigate its effect on the naturally occurring infection in man. Roehl in Spain and Mühlens in Hamburg and the Balkans were able to show that, even under climatic conditions which favoured the development of malaria, plasmochin was therapeutically effective; and that, further, it possessed the unique property of being fatal to the gametocytes of *Plasmodium falciparum*.

Once having established these fundamental facts, it became necessary to study the therapeutic properties of plasmochin in detail. The protean manifestations of malaria rendered it necessary that this work should be carried out in different malarial districts scattered widely over the globe, and with the co-operation of critical workers.

It is universally recognized nowadays that atabrin and plasmochin are effective against malaria, but, in spite of a mass of work which has been published dealing with the action of these substances, there still exists a great deal of confusion, in many respects, with regard to their value in therapeutics, sanitation and prophylaxis. A decade has elapsed since the discovery of plasmochin. Since then I have had opportunities of exchanging views with most of the experts in malarial research, and, directly or indirectly, I have become acquainted with their experiences and opinions; I have discussed their problems with them and learned their results. Basing my remarks, therefore, on the combined experiences of hospital, laboratory and practice, I would like to give you a review of matters as they stand to-day.

*By invitation of Professor Giuseppe Bastianelli, Rome, this paper was delivered by the author in the Istituto di Malariologia in Rome in the August of 1934, and will also be printed in German language in the *Rivista di Malariologia*.

† British protozoologists use the word 'gametocytes' for the sexual forms of the malaria parasites in the human host, reserving the word 'gametes' for the mature stage in the mosquito.—Editor, I. M. G.

Of critical importance for the elaboration of these new compounds was the combination of basic aliphatic side chains with the nucleus of heterocyclic compounds, using nitrogen as a link. A glance at chart I will show you that atebrian, plasmochin and quinine are

CHART I

all derived from 6-methoxy-quinoline which in atebrian is changed to acridin by combining it with a benzol nucleus. The side chains in atebrian and plasmochin are identical, alike in structure and in the nature of the linking member. The positions of the side chains on the ring system differ in plasmochin and quinine, but are analogous in quinine and atebrian. Variations in the structure, position and substitution of the ring system and side chains lead to changes in the nature and intensity of the drugs' action.

In chart II where infection with *Plasmodium falciparum* is used as the example, we have a schematic

CHART II

Subtertian Malaria Malaria Tropica

résumé of the type of action which is exerted. Quinine and atebrian act in the same way on the forms of the asexual cycle only. They are devoid of any direct effect upon the sporozoites and gametes. Plasmochin exercises a profound influence on gametes, displays only a slight effect on the forms of the asexual cycle, and is without action on sporozoites. The action of the three compounds on *Plasmodium vivax* and *malariae* is not so sharply defined. Atebrin, plasmochin and quinine, it is true, possess no action against sporozoites, but, just as quinine and atebrian act on gametes as well as on schizonts in these cases, so plasmochin, while retaining its action on gametes, displays a marked effect on the schizonts.

The work of Kikuth on *Halteridium* infection—using the rice finch as a laboratory animal—has enabled us

to demonstrate, with a fair degree of precision, the presence of any action on the schizonts and gametes, so that it is now possible to gain some idea in the laboratory of the type of action which a new compound will exert. Following up a suggestion of James, experiments on canaries were developed in a manner which rendered it possible to search for a compound possessing a direct action on sporozoites, and also for a causal prophylactic in the strictest sense of this word; but these experiments have so far produced no result. There have been modifications in the plasmochin and atebrian groups made in our scientific laboratories at Elberfeld, but up to the present we have not succeeded in finding a relative of plasmochin with a pure anti-schizont action, or a member of the atebrian group acting on gametes, or in preparing a compound which might be described as a 'pantherapeuticum'.

We may now take it as definite that we have succeeded in synthesizing drugs which are effective against malaria. Like quinine, these attack a more or less specific point of the developmental cycle of the malarial parasite. We therefore speak of anti-schizont drugs, and of anti-gamete drugs, although the fields of action of the various drugs overlap to a greater or lesser extent.

These facts have stimulated and illuminated further work on malaria, both scientific and practical, in many directions. All this work, particularly the elaboration of laboratory test methods, has been made possible only by applying the results obtained by all those investigators, who, since the discovery of the malarial parasite, have provided clear facts as exemplary working bases. In recent times these test methods have been extended still further by laboratory experiments on ape malaria, by means of which, for instance, Chopra and Das Gupta, Nauck and others have demonstrated the superiority of atebrian over quinine in respect of intensity of action.

These experiments do not permit any definite conclusion to be drawn as to the action which would be exercised in malarial infections occurring naturally in man. But another fortunate circumstance came to our assistance—the possibility of making preliminary tests on general paralytics infected with malaria. Sioli, employing the strain of *Plasmodium vivax* which Wagner-Jauregg had used in the treatment of general paralysis, successfully carried out such experiments both with plasmochin and atebrian. In their classical work on the testing of quinine, Warrington Yorke and James had already availed themselves of the opportunity of working on general paralytics infected with malaria. James has developed this work still further, and has founded a malarial research station at Horton. There can be no doubt of the extraordinary value of such investigations on a disease the course of which can be exactly controlled, investigations with the precision of laboratory work. To-day it is even possible to utilize *Plasmodium falciparum*, *ovale* and *malariae*, as well as *Plasmodium vivax*, in such experiments.

In spite of this we were unable then, nor can we now, deviate from the point of view that even the results of tests on general paralytics infected with malaria do not permit us to draw any final conclusions which might be applied in practice. Clearly recognizing the situation, the Malaria Commission of the League of Nations also expresses the same point of view in the sub-title of the report on 'The Therapeutics of Malaria'—'Principles of treatment based on the results of controlled experiment'. However exactly controlled experiments on malaria in general paralytics may be, the sufferer from general paralysis is by no means a normal individual. The resistance and ability to react on the part of the host's body is gravely impaired as the result of infection of the central nervous system by the spirochæte. We know that, during the course of his disease, the general paralytic deteriorates more and more, and that he is very liable to secondary infections, such as septic

diseases, pneumonia, etc. The favourable therapeutic effect of malaria on general paralysis, which occurs now and then, is evidence of the profound mutual influence which these two diseases exert upon one another. Moreover, the general paralytics, on whom the anti-malarial drugs are tested, exist under far more favourable circumstances than the individual infected naturally. He is in a temperate climate, well nourished, and adequately protected from adverse conditions, such as cold, and bodily exertion. There is also a fundamental difference between the modern method of infecting general paralytics in which a large number of heavily infected anopholes are used one or more times, and the definitely not too intensive infection which occurs in nature.

A short example may serve to show how easy it would be to draw false conclusions, if the experimental results obtained from therapeutic malaria were taken as applicable in ordinary practice. It might be inferred from the work of Ciucu on general paralytics infected with malaria, and from that of Swellengrebel on volunteers who were heavily infected artificially, that the combination of plasmochin with quinine did not affect the relapse rate. To give an instance from practical experience, however:—The malaria station in Kasauli (British India) was obliged to close down on account of the systematic use of the very combination mentioned; so great was the fall in the number of malarial cases that there remained no more cases for admission to the hospital. Sinton and Bird and Manifold and Jarvis have reported in detail on the results obtained in Kasauli. Unfortunately the report, already mentioned, of the League of Nations' Commission on Malaria, cites Sinton's earliest work incompletely; it fails especially to show that, following treatment in Kasauli with quinine, about 70 per cent of relapses occurred as against only 8.5 per cent after plasmochin + quinine.

Much as we may congratulate ourselves on the excellent possibilities for research which malarial infection in general paralytics presents, we must guard against drawing one-sided conclusions. We may consider ourselves fortunate in possessing in therapeutic malaria a prolonged laboratory test which furnishes us with a guide, and enables us to experiment on natural malaria in a critical atmosphere. It was clear to us that in establishing the value of plasmochin and atebrian we must tread the same paths which had proved of such value in testing other preparations. The action of new preparations must, first of all, be worked out by animal experiments after which their worth in action must be confirmed in practice. No matter whether it is a drug, such as a stimulant, a hypnotic, or an analgesic that is being dealt with, or substances which are aetiological effective in infective diseases, animal experiments will yield only certain broad facts with regard to dosage and action. We know that differences in the metabolism of the various species of laboratory animals may determine fundamental differences in the pharmacological action of drugs. I need only refer, in this respect, to the action and assaying of digitalis in the frog and cat as compared with its actual action in man; and to the fact that hypnotics act differently in the carnivorous dog and in the herbivorous rabbit. You are also aware that the most effective analgesic, morphine, for man gives rise to a state of intense excitement, even in the smallest doses, in the cat. Thus we see, in all respects, that the *milieu*, or the host, on which they act, plays a part of great importance in determining the action of an arsenical preparation.

It is clear from all this that although the practical test must logically follow the laboratory experiments, it is often only on the practical application of a drug that therapeutically valuable properties are revealed, properties which were not to be foreseen in the laboratory stage. I would remind you, for instance, of the hypnotic 'luminal', which is related to 'veronal', and

which in practice proved to be an anti-epileptic. Completely analogous was the discovery in practice of the gametocidal properties of plasmochin, and of the fact that a combination of plasmochin with quinine led to a very considerable shrinkage in the relapse rate.

We therefore applied plasmochin and atebrian in practice in accordance with these considerations. In the beginning, shortly after the discovery of plasmochin, when its clinical tests were due to be carried out, I found it extremely difficult to find collaborators and a suitable field for work. At that time, anyone claiming to have an effective anti-malarial specific, which was not connected with quinine in some way or other, encountered the deepest mistrust. The actual words spoken to me by the chief of a well-known clinic—he had at one time worked under Paul Ehrlich—were: 'You may spare yourself the trouble of searching for a substance effective against malaria—you could not prove it. It would be impossible to confirm its anti-malarial action; that is why Ehrlich gave up attacking this problem. It would be of far greater importance to find, for instance, a new gold preparation effective against tuberculosis, or a specific for Malta fever. But, if you must do the other, you had best test this compound in general paralytics infected with malaria; or better still, you might try if this drug would prevent the infection of red blood corpuscles by sporozoites *in vitro*'.

In spite of this, there exists to-day an immense amount of material, difficult to review and to appraise, but which represents for the most part the careful work of renowned investigators and practitioners. I shall endeavour to give, as clearly and as simply as possible, a critical account of this work, which, I hope, will stimulate still further research so that obscure and controversial points may eventually be cleared up.

As I have already shown in chart II, the gametes of *Plasmodium falciparum*, while they are unaffected by quinine, are destroyed in a few days by plasmochin given in daily doses of 0.03 g. (gr. $\frac{1}{2}$). At the same time plasmochin exerts a slight, but definite effect on the forms of the asexual development of this protozoon. The action of plasmochin on the individual developmental forms, i.e., gametes and schizonts, in infections with *Plasmodium vivax* and *malariae*, is not so well defined as in that with *Plasmodium falciparum*. For this reason, the effect of plasmochin in the treatment of acute attacks of tertian and quartan malaria is greater and sets in more rapidly than in subtertian malaria. To obtain these results, using plasmochin only, in acute attacks, relatively large daily doses are necessary, namely: 0.06 g. (gr. 1) in tertian and quartan malaria, and 0.06 to 0.08 g. (gr. 1 to 1 $\frac{1}{2}$) in subtertian malaria. However, if continued over 5 to 7 days, these doses give rise, comparatively frequently, to unpleasant toxic symptoms, such as abdominal pains and transitory cyanosis. Nevertheless, these trials were essential in order to learn the therapeutic effects of plasmochin.

The knowledge that plasmochin, generally speaking, acted more strongly on the gametes and less so on the asexual developmental forms than quinine, and *vice versa*, induced Mühlens to combine the two drugs. Practical experience has shown the proportion of quinine to plasmochin = 30:1 present in quino-plasmochin, to be the most suitable one. The normal effective daily dose of quino-plasmochin for an adult is 3 tablets increased to 4 [corresponding to 0.9 to 1.2 g. (gr. 13 $\frac{1}{2}$ to 18) quinine + 0.03 to 0.04 g. = gr. $\frac{1}{2}$ to $\frac{5}{8}$ plasmochin daily]. This combination of the two drugs would appear to bring about the optimum therapeutic effect, at the same time avoiding all danger of toxic symptoms.

Further practical experience has brought to light two additional facts: Firstly quino-plasmochin reduces the relapse rate to 5 to 10 per cent as compared with 50 to 70 per cent after treatment with quinine only.

These figures have been established as the result of the vast practical experience of workers of considerable authority; they are therefore scarcely open to doubt. It will suffice, here, to mention the extremely valuable work of Dixon, who observed over 600 cases from 10 months to 3½ years. These cases showed 4.18 per cent relapses among 215 cases of primary tertian, 4.7 per cent out of 141 recurrent tertian cases, and 2 per cent among the subtertian cases. On theoretical grounds alone, based on pharmacology and experimental therapeutics, it is easy to understand the increased action obtained by combining two weakly acting compounds. We know, for example, from the exact laboratory experiments of Kikuth, that a combination of individually ineffective doses of Germanin and Fouadin, respectively, will bring about cures in trypanosomiasis such as could not be attained with far larger doses of the components given singly. The theoretical considerations governing the formation of double combinations does not concern us here.

The second important fact was revealed by Barber. Even in the smallest daily doses, plasmochin is capable, without actually destroying them, of rendering the gametes of *Plasmodium falciparum* non-effective to mosquitoes.

Working on the West African coast together with Rice, Barber was able to prove that, by the method developed by him, he could reduce infection among mosquitoes to zero; and in this way, to a large extent, prevent re-infection in man. Barber's discovery was further developed by Missiroli in particular. At his suggestion Jerace and Giovannola carried out research in order to discover the smallest dose of plasmochin which would render the gametes of *Plasmodium falciparum* non-infective to mosquitoes for eight days. These workers found from their experiments that a dose of 0.02 g. (gr. $\frac{1}{2}$) plasmochin on 2 days in one week would suffice under all circumstances for the prevention of infection among mosquitoes, and would, therefore, interrupt transmission to man. Widely planned and carefully controlled experiments, extending over years, were carried out in Sardinia by Missiroli and Mosna. They were crowned with complete success in this respect, thus demonstrating by means of plasmochin the possibility of carrying out successful preventive work by the use of drugs.

When we began trying out atabrin in practice, the situation had become much easier than it had been in the early years of testing plasmochin. The mistrust of synthetically-prepared anti-malarial drugs had been conquered. As Peter showed, atabrin acts on the schizonts, so that its action, in the treatment of the acute attack, may be directly observed. It was found that atabrin corresponded, in its action, to quinine, so that it was unnecessary to give it in combination with the latter. The uncomplicated action of atabrin was thus made easily demonstrable. When given in the comparatively small doses of 0.3 g. (gr. $\frac{4}{11}$) daily, the effect of atabrin was at least as good and as persistent as a 21 days' course of quinine in doses of 1.0 to 1.5 g. (gr. 15 to 22½) a day. It appeared that these short courses of treatment with atabrin were also able to reduce the relapse rate after infection with *Plasmodium vivax*. Atabrin, however, does not reduce the relapse rate to quite the same extent as quino-plasmochin. In order, therefore, to obtain similar results in respect of relapse rate to those obtained with quino-plasmochin, it will be necessary to combine atabrin with plasmochin, or to follow treatment with atabrin by a short course of plasmochin. Like quinine, atabrin is ineffectual against the formed gametes of *Plasmodium falciparum*.

It is psychologically interesting that, since its introduction, atabrin has aroused far more interest than plasmochin, so that in many places it has been thought plasmochin might be somewhat neglected in favour of atabrin. This is readily understood when it is realized that the visible effects of atabrin in the acute attack are clear and unmistakable. On the

other hand, those whose work is guided by long views soon discover that atabrin and plasmochin are complementary in their actions; so that it is only by acquiring skill in the use of both weapons that perfect results can be obtained in the struggle against malaria. In addition to all this, every practitioner is aware that quinine still retains its value as a malarial specific, and will remember with gratitude the gifts which Nature has bestowed on us in centuries gone by.

So far I have only touched upon the subject of prophylaxis in malaria. The term 'prophylaxis' is a very elastic one, and has already taken on more than one shade of meaning. It is chiefly subdivided into clinical or symptomatic prophylaxis, and causal prophylaxis.

A clinical or symptomatic prophylactic is one which, while suppressing the clinical symptoms, allows a latent malaria to arise or to persist. Quinine is the prototype of such prophylactics.

A causal prophylactic may be called upon to fulfil various conditions. In the strictest sense of the word, it should denote an agent capable of destroying sporozoites the moment they enter the human body. So far we do not possess such an agent.

However, a drug may become in effect a causal prophylactic by acting with such energy on the forms evolving from the sporozoites and on the forms of the asexual development of the parasite that the development of a latent malaria is prevented. Plasmochin acts in this way to a certain extent, and, according to James, atabrin also. Atabrin, given to general paralytics for 6 days, prevented infection with *Plasmodium falciparum* entirely; and in the case of infection by *Plasmodium vivax*, the incubation period was prolonged for several months. There is no exact confirmation in practice of this prolongation of the incubation period, nor can we explain its occurrence scientifically.

Finally, the destruction, or sterilization of gametes, so that infection of mosquitoes with subsequent transmission of the disease to man does not occur, may also be described as prophylaxis. The term prophylaxis as used in this respect is equivalent to the expression 'prevention by drugs' (medikamentöse Sanierung), for which purpose plasmochin, especially if combined with atabrin or quinine, is to be recommended.

Having reviewed our present knowledge of the actions of atabrin, plasmochin and quinine, it is essential that we should now turn our attention to the pharmacology and toxicology of these drugs in view of the possibility of toxic effects.

Once again the general remarks, which I made with regard to animal experiments, apply here with equal force. Animal experiments merely give us a few facts to go on, an indication of the lines on which to proceed; results thus obtained cannot be applied directly to man. Symptoms may arise in man which are not observed, or cannot be reproduced, in animal experiments; conversely, it would be absurd to infer that effects seen in, say the frog, would necessarily appear in man. It will therefore be my task, here, to deal only with those pharmacological and toxicological phenomena which have a practical bearing upon the toxic effects met with in man.

Plasmochin may give rise to abdominal pains and cyanosis. So far, animal experiments have yielded no explanation for the abdominal pains. Plasmochin possesses no action on the mucous membranes or musculature of the digestive tract of even the most widely differing species.

Cyanosis depends upon a reversible reaction in which methæmoglobin is formed. This may be reproduced experimentally in the cat, but not in the rabbit.

In practice, cyanosis is generally seen when relatively large daily doses, 0.06 to 0.08 g. (gr. 1 to 1½), of

plasmochin are given continuously over fairly long periods. It is more likely to come on in a patient at rest in bed, than in one who is up and about, or at work. Mild cyanosis appears in a small percentage of cases when doses of 0.03 g. (gr. $\frac{1}{2}$) plasmochin are given daily, but it disappears rapidly and completely on discontinuing the treatment. Abdominal pains are especially liable to arise when plasmochin is taken on an empty stomach; they may, therefore, be readily avoided by taking the drug after meals.

These toxic symptoms show enormous individual variation. The literature from diverse parts of the world shows that, next to constitution and nutrition, race and diet are of the greatest importance, as are, in addition, the presence of complicating diseases, such as gastric ulcer, intestinal worms, and so forth. All these factors have to be taken into consideration by the practitioner.

Another fact, which is interesting because it depends on pharmacological principles and is therefore of value in therapeutics, is that simultaneous administration of plasmochin and quinine improve tolerance to the former. Meimmi was the first to observe alterations in the pulse rhythm set up by plasmochin in very rare cases. Eichholtz showed, by animal experiments, that this was due to disturbance of conduction which could be completely abolished by quinine. These disturbances of rhythm are so rare in man that they are of no practical importance.

For the sake of completeness it must be mentioned that, among the many millions treated with plasmochin, some 20 fatal cases are described in the literature. These fatalities are more or less justly attributed to plasmochin, although it is not altogether clear to what extent these effects might have been due to hypersensitivity to quinine, which may have been taken at the same time. In these exceptional cases, an acute hæmolytic occurred even with small doses of plasmochin, similar to but not identical with that which occurs in blackwater fever following quinine. The number of these cases is infinitesimal in comparison with the number of cases of blackwater fever. In spite of many laboratory experiments, we have been unable to find a clue to the cause of this rare occurrence. I refer those who are interested in the subject to the excellent work of Amy, which I am in a position to confirm. Amy's work has proved that fluctuations in the toxicity of plasmochin do not occur, and cannot, therefore, be responsible for these altogether rare catastrophes.

Abdominal pains are occasionally experienced after taking atebirin, but they are much less frequent and not nearly so severe as those following plasmochin. The remarks on plasmochin in this respect apply equally here. After prolonged administration, atebirin gives rise to a yellow discoloration of the skin which is due to the formation of an acridin pigment. This pigmentation is of no clinical importance, it does not give rise to photosensitiveness, and disappears after a time. After painstaking research, it may be stated as definite that atebirin does not affect the liver in any way and never gives rise to jaundice. Atebrin has practically no effect upon the circulation: fatal cases are unknown. The best proof of the large margin of safety possessed by atebirin was furnished by the unintentional mass experiment of an official distributing centre, where, owing to a mistake in the label, 10 times the normal daily dose, *i.e.*, up to 3.0 g. (gr. 45) of atebirin, was dispensed. Nothing more serious than acute abdominal pains occurred. Even in such large doses atebirin did not give rise to methæmoglobinæmia nor act upon the red blood corpuscles in any way. Practical experience has shown that atebirin is particularly suitable for the treatment of malaria with blackwater fever, or with any tendency thereto.

Another fact of importance in practice is that, in many parts of the world, the simultaneous administration of 0.03 g. (gr. $\frac{1}{2}$) plasmochin and 0.3 g. (gr. 4½)

atebrin daily, gives rise to more or less violent abdominal pain in a high percentage of cases. Simultaneous medication may yet be made possible by altering the proportions of the compounds, or by special methods of encapsulation. Experiments are being performed with this end in view. For the present, I can only advise treatment with atebirin followed up by a course of plasmochin.

What guides do the facts at our disposal provide, and what are the advantages of treatment with synthetic malarial specifics?

I am in complete agreement with the pronouncement of the League of Nations' Commission on Malaria to the effect that, depending on local conditions and the end to be attained, profound modification and individualization of treatment are necessary if the best results are to be obtained in the most economical manner. Adults react differently from children. Marked differences in constitution, nutrition, mode of life, etc., exist between Negroes, Chinese, Javanese, Indians, Europeans, and so on. The properties of the protozoa in addition to those of the infected person may determine great differences in virulence and resistance. Climate, and opportunities for infection, play a large part with regard to the course of the disease, and much else. But the practitioner is accustomed to reckoning with such factors. He will take them into consideration when, in addition to quinine, the old and trusty sword of his fathers, he wields the new and sharper weapons, atebirin and plasmochin, just as we have learnt to drive cars, or fly planes, instead of continuing to plod along with the faithful horse.

In order to make the fullest use of the possibilities at our disposal, some scheme is necessary which can be modified according to circumstances. The following general scheme is put forward as a basis for treatment and preventive work:—

Atebrin + plasmochin

For the treatment of acute attack (first infection and relapse):—

5 to 7 days — 0.3 g. (gr. 4½) atebirin daily.

3 to 4 days — interval.

3 to 5 days — 0.03 g. (gr. $\frac{1}{2}$) plasmochin daily.

For prevention (general prophylaxis):—

Two days a — 0.02 g. (gr. $\frac{1}{2}$) plasmochin per day. week throughout the whole of the malarial season.

This scheme may be modified, and eventually reduced, depending on the end in view, the amount one wishes or is able to spend, and the local conditions under which the work is to be done. For example, those who do not wish to carry out preventive work will drop the after-treatment during the whole of the malarial season, while those who do not believe that plasmochin reduces the relapse rate after tertian fever will prefer treatment with atebirin only. But all who wish to reduce medication in this way must be quite clear on one point, and that is, that it is only by doing everything that is necessary that perfect results can be obtained. Those who do less must be content with inferior results.

I have already shown the kind of result one may hope for at best. The practitioner will at once ask, what is the relation between these results and cost, and what are the advantages of using synthetic compounds rather than quinine?

I can only reply that, on paper, figures may be made to prove anything. For example, comparing the effective dose of atebirin, 0.3 g. (gr. 4½) a day, with that of quinine, 1.0 to 1.5 g. (gr. 15 to 22½) a day, atebirin works out a little dearer than quinine. At the other extreme, if a 5-day course of atebirin is taken

to be the equivalent of a 21-day course of quinine, then atabrin comes out considerably cheaper. The truth lies at some intermediate point whose precise position will be determined by local factors. The calculation should take into account the saving in days in hospital, the gain in days at work, reduced personal expenses and cost of nursing, the smaller relapse rate and avoidance of re-infections; in short, all those factors must be allowed for which are of importance in assessing the value of a temporary against a permanent cure.

We hope the young twins, atabrin and plasmochin, will work energetically together to bring about the end which their worthy, elder brother, quinine, could not do alone—that is, the prevention of malaria by drugs. Despite their youth, atabrin and plasmochin are sufficiently modest to acknowledge the enormous success attained by technical preventive methods such as petroleum, Paris green, gambusia, etc., and above all by the sanitation of the soil. We have a classical example in our immediate vicinity at Agro Pontino, where, side by side with the struggle against malaria, work, bread, and the conditions of existence are being created.

The same things hold good for the prevention of malaria, which are essential in the lives of men and nations. Peaceable co-operation is of far greater value for the general progress than a conflict in which only the parasites gain.

ERRATUM

Through a transcribing error, in Dr. Dias's paper, 'A Fatal Case of Bronchial Asthma', that appeared in our January issue, in line 23, p. 29, the words 'status lymphaticus' were printed; the words should obviously have been 'status asthmaticus'.

Referring to the author's original manuscript we find that the word he has written is undoubtedly 'asthmaticus', but we take this opportunity of pointing out that such errors could be obviated to a large extent if contributions were sent in typescript.—Editor, I.M.G.

Indian Medical Gazette

FEBRUARY

THE TUBERCULOSIS PROBLEM IN INDIA

THE extension of tuberculosis in this country is a matter that has been repeatedly brought to the notice of both the general public and the medical profession during the last three decades. In 1909, Rogers found active tuberculosis to be the cause of death in 18.3 per cent of a series of 3,000 post-mortem examinations in Calcutta; reference to health reports since this date will show that sanitarians have been fully aware of this danger, and, though they may have instituted few practical measures to ward it off, they have at least the satisfaction of having issued warnings.

Until quite recently little notice has been taken of these warnings, for a number of reasons that are easy to appreciate; in the first place emphasis has usually been laid on the future, rather than the present danger of the disease, secondly, there have been so many other more dramatic diseases to distract attention, and finally, tubercularization was accepted as the inevitable accompaniment of industrialization and urbanization of the population and there seemed to be no obvious way of dealing with the problem other than in general terms, such as the rectification of undesirable social habits and the improvement of general hygiene. Consequently tuberculosis has attracted the attention of the critical rather than the constructive politician and the demand has usually been that the 'government should do something about it'.

However, during the last few years a very distinct change has come over the situation. It is now being realized that, whether the bogey of a future widespread 'epidemic' of tuberculosis is real or not, the present position is bad enough to demand immediate action; that, even if there are one or two more important diseases from the point of view of mortality, we know how to prevent and/or treat these and much effort is being made in this direction, whereas nothing is being done about tuberculosis; that, even if tubercularization of the population is inevitable, with the example of other countries before us, we should be able to devise some means by which this process can be controlled and directed; that, if there is no *obvious* way of dealing with the problem, then it is time that we abandoned struthious tactics and looked round for some way of escape from this impasse, which way, if not obvious, is at least not inconceivable; and finally that the problem is essentially one in which the government—even if they were omniscient and omnipotent—could not effectively make the first move, that the onus of doing this falls on to the general

public through their philanthropic societies, and that it is the duty of the medical profession to guide and help them in this work.

To show the seriousness of the tuberculosis problem in India to-day, it is only necessary to quote from the last annual report of the Public Health Commissioner:—'Assuming that two per cent of the total deaths are due to tuberculous disease then nearly 150,000 persons die annually from this infection. But some experts hold that ten per cent is nearer the truth, and, on that basis, tuberculosis deaths would number 650,000. The latter is almost certainly an exaggerated figure, but it is probable that the actual number of deaths lies somewhere between these two extremes and, even taking the lesser figure, the situation is serious enough'.

The actual figures that he is able to quote from the returns of the provinces where the disease is notifiable give no indication of the gravity of the position. Further, they indicate that the disease is mainly an urban one, whereas in the opinion of many civil surgeons and administrative officers whose duties take them into rural as well as urban areas it is in the former that the position is most serious. The village chowkidar has not yet learnt to distinguish the emaciation of the phthisical from that of the chronic malaria subject, nor blood-stained sputum from the rusty sputum of pneumonia, so that nearly all deaths from phthisis are returned under the headings 'fever' or 'respiratory diseases'. Even in urban areas correct diagnosis of the cause of death falls very far short of the ideal, and in one area where a special investigation was carried out to check this particular point, it was found that nine per cent of the 'fever' deaths and twenty per cent of the 'respiratory diseases' deaths were due to phthisis, and that half the deaths due to phthisis had been returned as due to 'fever'.

It must be obvious that, if this state of affairs can exist in an urban area where medical aid is available—though it may not be taken advantage of—we cannot get much comfort from the low figures for deaths due to tuberculosis in the provincial returns. In many western countries the centre of gravity of the tuberculosis problem has now moved from the towns to the villages; in India with its huge rural population, living in large family communities whose members often sleep in closed rooms with as little cubic space per person as they would if they were living in a town, the centre is here already; urbanization has provided the spark, but it will be in the villages where the fire will eventually burn most fiercely.

Referring to the cause-of-death returns the Public Health Commissioner says 'The value of the recorded figures is greatly vitiated by the fact that correct diagnosis of the cause of death is rarely obtained and numerous deaths from tuberculosis are without doubt registered, both

in towns and in villages, as due to fevers or respiratory disease. Indeed, it may safely be assumed that the majority of the deaths from tuberculosis are registered under one or other of these groups. There exists also the general tendency to conceal the cause of death in tubercular cases for fear of social disabilities or of quarantine and other disinfection measures'.

There are three planes on which this problem can be tackled, the social, the medical relief and the research, and if any success is to be achieved it must be tackled in all three simultaneously. It is not suggested that work on these three separate planes should be independent; on the contrary it is most essential that there should be as complete co-ordination as possible, and the public health department with the aid of the voluntary societies should be the co-ordinating agency.

If the Public Health Commissioner cannot give the tuberculosis death rate more exactly than as 'between two and ten per cent of total deaths'; it is apparent that one of the first essentials is more exact information on the incidence of this disease, in the population as a whole and in its various elements. Even for limited communities we have little more accurate information. There is reason to believe that the death rate from this disease amongst women between the ages of 15 and 40 is very much higher than amongst the rest of the population (but even this information is based mainly on direct evidence) and from this it is argued—almost certainly correctly—that the purdah system and early child-bearing are contributory causes; other data regarding the incidence in different age groups, in different communities, amongst groups of people on various diets, *e.g.*, vegetarian and non-vegetarian, poor and good, etc., amongst different populations, urban and rural, hill and plain, factory workers and outdoor labourers, and so on, would provide information of immense value in apportioning the blame to the various contributory social factors. In the same way information on the relative susceptibility of these populations, which can be obtained with a fair degree of accuracy by means of the tuberculin tests, would be of great assistance. This is the type of 'field' research work that should be undertaken if not by medical officers of health at least in co-operation with the health departments.

Until a few years ago tuberculosis was not considered a suitable subject for research work in this country; the argument against it being that in other countries so much work is being done, the results of which can be applied here, that it would be better to devote our energies to diseases peculiar to India; the first part of this argument can be used equally well in favour of doing research work on tuberculosis in this country, or alternatively the whole can be used as an argument against work on some of the diseases that are considered suitable subjects

for major enquiries. Another argument used recently was that we know that unhygienic conditions of living and poor food are responsible for tuberculosis and that all we have to do is to apply the rules of hygiene; it might equally well be said that we know that anopheles mosquitoes carry malaria and that therefore we should give up malaria research and just destroy all the anopheline mosquitoes in India. It would certainly not be any more impossible than housing and feeding properly three hundred and fifty million people. We do not even know what would be ideal housing for the peoples of this country; some of the essays at this problem in the big cities in India have been disastrous. Problems that have been worked out in Camberwell cannot be applied in Cathay—or in Hindustan. One investigation that has been carried out has been on the prevalent types of tubercle bacillus, and it has been found that here the state of affairs is quite different from that in Europe. This observation has an important bearing on the ætiology of the disease, but it is quoted here only as an example of how even repetition in this country of investigations that have been carried out in other countries may throw light on our own particular problem. As Dr. Ukil, who has done much to stimulate both research and social work on tuberculosis in India, has pointed out, there are many other instances in which 'comparative' investigations of this nature would almost certainly supply important data.

The facilities for the special treatment of tuberculosis are at present grossly inadequate; there are only twenty sanatoria—some of them very ill-equipped—in the whole of the country, and an even smaller number of special tuberculosis dispensaries. In the hospitals in the large towns there are seldom any special wards set aside for this disease.

This is an aspect of the problem that seems to make a special appeal to the Indian philanthropist and we have no doubt that in time money will be found to endow sanatoria and dispensaries, but in the meanwhile special arrangements should be made in established hospitals for the treatment of tuberculous patients and for the training of students in the modern methods of the treatment of this disease. 'But', as the Public Health Commissioner says, 'it must be realized that the way to victory does not lie, except in small part, in the provision of clinics, hospitals and sanatoria. Money spent on such institutions will be money largely wasted unless the social factors involved are studied and then attacked with vigour. In the practice of more hygienic methods of living, in the provision of ample and nutritious food supplies and generally in a wider appreciation of the dangers inherent in harmful social practices will be found the way to a gradual decrease of this scourge of civilization and generally to a healthier and happier people'.

Some of the provincial tuberculosis societies and associations, notably the Tuberculosis Association of Bengal, have done valuable pioneer work, particularly in the way of publicity and education, and now the King George's Thank-giving Fund, which was founded three years ago, has given the subject an all-India status and has already done much to stimulate and

assist the provincial organizations. The recent conference that was held under the auspices of this fund should do much to stir the imagination of the general public and interest them in this problem. There is an enormous field for work of this kind and it is the type of work in which all educated people can and should assist.

Commentaries

RECENT ADVANCES IN OPHTHALMOLOGY

THE last edition of *Recent Advances in Ophthalmology** by Sir Stewart Duke-Elder is a worthy successor to the previous ones, and the author has fulfilled his promise of introducing new subjects while leaving out others originally dealt with in order to maintain reasonable proportions. The work should be available to all ophthalmologists, not only on account of the recent advances presented but also because of the extensive and valuable references to literature. The arrangement in this edition is excellently adapted to review in perspective the great problem of glaucoma, the first five chapters, part I of the book, representing the foundations on which the modern conception of this condition, as set forth in chapter XII, is built.

Chapter I deals with the vascular circulation; the arterial, venous, and capillary circulations, and their pressures in the eye. It will be remembered that as in other organs the circulation of the eye may be influenced by two factors: that of the general circulation on the local state of the intra-ocular vessels, and the independent activity of the vessels themselves. That portion of the chapter which is new concerns itself chiefly with the control of the contractibility of the small vessels by two mechanisms, nervous and chemical. While working in full interrelation, the first, under the governance of the central nervous system, is a coarse adjustment, and the second, controlled by local conditions, forms a fine adjustment. The vaso-constrictors of the uveal tract are supplied by the sympathetic; with regard to the retinal vessels the matter is not settled. There is no evidence however that the autonomic system—which is partly responsible for vaso-dilatation through its parasympathetic outflows—supplies vaso-dilatator fibres to the eye. Vaso-dilatation may occur as an antidromic phenomenon of the fifth nerve by a local sensory stimulus and a short-circuit axon reflex; or by a more general reflex involving the central nervous system. Axon reflexes acting through sensory nerves and involving vaso-dilatation through liberation of histamine are local and retained after excision of the Gasserian ganglion. Such is the mechanism of the increased intra-ocular pressure in trauma. Axon reflexes through the sympathetic involve vaso-constriction, e.g., a bloodless iridectomy in a healthy iris. The direct action of light brings about a reflex vascular tonicity, and dark adaptation the reverse, quite independent of the perception of light; it occurs in blind eyes. Chemical control is by:—(a) constrictor hormonal substances, e.g., pituitrin (a constant or tonic constrictor) or adrenaline (a rapid emergency mechanism), and (b), dilator substances locally produced by the tissues typified by histamine. The latter are products of normal metabolism. This second

mechanism is the most powerful and, in conflict with the former, dominates it. The histamine-like substances produce the 'triple response' of Lewis:—primary and local capillary dilatation, local increase in capillary permeability, and widespread dilatation of neighbouring arterioles. The histamine output is controlled by antidromic impulses descending in the sensory nerves. The triple response may be obtained by the trauma of stroking the iris, similarly it follows temporary blocking of the venous circulation, the action of toxins and capillary poisons of heavy metals, etc.; reactions of extreme importance in ocular pathology. After a marked histamine reaction any attempt to constrict the capillaries and restrict their permeability is ineffective, ('unresponsive state'), e.g., by adrenaline in a marked congestive glaucoma; on the contrary a 'refractory state' is produced in which adrenaline makes matters worse.

Permeability.—The capillaries of the eye are very impermeable to colloids, more so than laboratory animals and much more so than other human capillaries. This provision of nature is designed for the maintenance of an optically homogeneous intra-ocular fluid. Dilatation of capillaries, as a rule, produces increase of permeability to colloids, e.g., after paracentesis. This statement is not absolute, e.g., excision of the cervical sympathetic ganglion causes intra-ocular capillary dilatation but decreased permeability. Permeability is increased by various stimuli, the most common of which are histamine-like metabolites, bacterial toxins, inflammatory products, direct action of radiant energy, adrenalinic (in small doses), dionine, atropine, pilocarpine, etc.

Chapter II deals with the intra-ocular fluid, a subject about which the author has contributed much authoritative work. The text is practically identical with that of the previous edition.

Chapter III on the vitreous body refers to some of the author's latest work, as well as to other new matter and may advantageously be dealt with at some length.

Chemically the vitreous body may be regarded as a gel formed by a combination of the intra-ocular fluid with the muco-protein and residual protein (the two non-hæmatogenous constituents, shown in the author's table as supernumerary to the hæmatogenous constituents of the aqueous). The muco-protein probably functions in maintaining transparency. The residual protein has the power of gel formation even in extreme dilution. In composition the aqueous and vitreous are chemically almost identical and the apparently great difference in nature between the humours is due to these two substances, which, adsorbing water and swelling up in solution, give properties of viscosity, elasticity, and solidity, a state termed a 'gel', in contradistinction to the more dispersed or fluid state, termed a 'sol'. The intimate structure of a 'gel' is still doubtful, but according to one view the complex colloid particles (micellæ) are separated and surrounded by fine films of liquid, and arranged in a definite pattern, e.g., minute fibrillæ

* *Recent Advances in Ophthalmology* by Sir Stewart Duke-Elder, D.Sc., Ph.D., M.D., F.R.C.S. Third edition, 1934. J. & A. Churchill, Limited, London. Pp. x plus 434, with three plates (two coloured) and 150 text-figures. Price 15s.

composed of strings of molecules. These particles become hydrated, and when sufficient water has been taken up from the solution, gel formation occurs. The swollen gel particles then come to occupy nearly the whole of the volume of the colloid-water mixture. Conversely if sufficient water is lost, swollen fibrillæ of ultra-microscopic size separate out and coalesce in aggregates, to form fibrils of microscopic size, eventually developing a fine felt of long, white, fibres—a curd or 'coagel'. Recent work with the ultra-microscope is still indefinite, but it seems evident that the fresh vitreous (like many colloids) is an amorphous gel; not a cellular tissue but a cell product derived from the epithelial tissues surrounding it. The appearances seen and described heretofore in histological preparations correspond to a coagulation process in any dilute inorganic gel.

Local variations in structure.—In the region of the ciliary body there is a coarser aggregation of fibrillæ, which anteriorly differentiates out to form the zonule (embryologically the tertiary vitreous). Immediately behind the lens is the narrow retrolental space prolonged as a tubular extension—the canal of Cloquet—to the disc. This, the embryonic primary vitreous, is composed of the finest fibrillæ widely spaced (optically empty). It is delimited by a funnel-shaped zone of condensation, the hyaloid membrane in front, the wide flat tunnel mouth, continuing posteriorly into the canal of Cloquet, its neck. The main bulk of vitreous, the embryonic secondary vitreous, separated from the primary vitreous by these condensations, is intermediate in consistence. These layers are not true membranes, but condensations such as may occur on the surface of any colloid solution. The embryonic secondary vitreous, constituting the bulk of the hyaloid body, is surrounded laterally by a condensation in contiguity and continuity with the internal limiting layer of the retina.

Gels are of two types, according as the water which combines with the colloid particles is 'reversibly' united or not. There are non-reversible inelastic gels, and reversible elastic gels capable of swelling and deturgescence. They are differentiated by a study of the vapour pressure isotherm. Examination of the vitreous shows it to be a reversible, elastic gel, showing no 'opacity point', and of a hydrophilic nature (Duke-Elder, 1930). The vitreous gel can combine reversibly and freely with water so that it may swell or shrink.

The elasticity of the vitreous gel.—The behaviour of the vitreous body in important clinical conditions where it breaks down (degenerative states), or swells (glaucoma), cannot be interpreted without an elucidation of the physical changes that determine its conduct, founded on accurate measurement of the consistency of its structure. The importance of such work in relation to detachment of the retina is obvious. The technical difficulties of such a research are great. Duke-Elder and Robertson (1934) investigated the movements of a nickel particle placed in vitreous—contained in a cell on the microscope stage—by a micro-manipulator and activated by an electromagnet. Two types of movement are observed:—(a) initial rapid (instantaneously reversible), illustrating the elasticity of the gel, and (b) subsequent slow displacement or 'creep' (irreversible). Acidification of the vitreous produces an increase in the former property, so that the vitreous behaves more like an elastic solid and 'creep' is diminished. This is due to withdrawal of water from the fibrillæ, although not sufficient under the experimental conditions to modify the ultra-microscopic appearances of the gel.

Anisotropism.—The vitreous in mass is not isotropic, but shows an arrangement of lines of strain when forces are applied. The residual protein, the gelable constituent, is developed from the retina. [There seems to be a slight confusion in the text here which is interpreted as follows.]

The vitreous frequently retains an intimate association at the sites of development of residual protein particularly at the ora, so that in pathological specimens the internal limiting membrane may sometimes be observed to leave the retina and adhere to the vitreous. It is possible therefore that in pathological states of the retina the lines of force, due to parallel orientation of the micellæ of the vitreous gel, may determine a tear or detachment.

Turgescence and deturgescence.—The fundamental problem, forming the basis of study of the physico-chemical properties of a gel of protein constitution, is the determination of the iso-electric point. The proteins are ampholytes capable of acting as acids or bases under different conditions. The intermediate point, at which the tendency to carry a positive or negative charge is equalized and the protein is electrically neutral, is the iso-electric point. At this point ionization, conductivity, osmotic pressure and turgidity are minimal. Consequently these properties will vary if the reaction is varied on either side of the pH at which they are minimal. A turgescence curve for the vitreous shows five zones: An acid zone where turgescence is maximal (pH 1 to 4), an iso-electric zone (pH 4 to 6) where the curve falls to a minimum, a neutral zone (pH 6 to 8) in which the curves rise to a sub-maximum short of pH 8, a zone of instability (pH 8 and 9) in which the turgescence may rise but generally falls, and an alkaline zone about pH 9 showing another sub-maximal rise and then a sharp drop beyond pH 9.5. Of more immediate interest is the behaviour of the vitreous gel mass in the globe under varying conditions, since changes in the gel volume will be reflected in the variation of the intra-ocular pressure. The author found a minimal volume (iso-electric point) between pH 4 and 5, thereafter a rise until pH 8, between pH 8 and 9 a zone of instability in which the gel may break down, beyond pH 9 gelation is again stabilized and volume increased, until after pH 9.5 the volume sinks rapidly to a minimum on the alkaline side of pH 10.

The instability of the vitreous body.—The vitreous homogeneous gel is in a very unstable dynamic equilibrium, the consistence of which is readily destroyed by the slightest mechanical insult. *In vitro* it tends to break down if subjected to a pressure of 1.2 mm. water. A similar gel-sol transformation occurs under the influence of acid and alkaline solutions and appears to occur clinically with any upset of the vitreous metabolism. In such cases (clinically familiar), fluid separates from the gel leaving it shrunken and interspersed with a felt-work of fibrils or gossamer-like floating membranes, representing depositions of residual protein.

Chapter IV on the intra-ocular pressure contains a considerable amount of new material.

The intra-ocular pressure is determined by the hydrostatic pressure in the capillary bed, minus the difference in osmotic pressure between the aqueous and capillary plasma. The normal equilibrium level, 20 to 25 mm. Hg., is such as to favour optical efficiency. Variations in intra-ocular pressure may result from:

- (a) External pressure on the globe.
- (b) Altering the equilibrium level, by
 - (1) raising or lowering the capillary blood pressure,
 - (2) varying the difference between the osmotic pressure of aqueous and plasma.
- (c) Varying the volume pressure inside the almost rigid sclerotic, by
 - (1) varying the dilatation of the uveal capillaries,
 - (2) varying the quantity of the aqueous,
 - (3) varying the volume of vitreous or lens.

External pressure.—The normal tone of the extra-ocular voluntary muscles maintains the intra-ocular pressure at about double that which would exist were they paralysed. Stimulation of these muscles raises the intra-ocular pressure, as also does contraction of

the lid muscles. The plain muscle of Müller acts similarly but only to a slight extent in man. Artificial pressure gives a rise, followed by a fall as aqueous is expelled through the angle, succeeded by a rise due to capillary dilatation.

Diurnal cyclic variation.—Highest in early morning before rising, it falls during the day and rises again during the night to its highest peak before waking; it is probably due to greater activity of muscles during the day.

Variations with the blood pressure.—Ultimately the height of the pressure in the intra-ocular capillaries determines the level of the intra-ocular pressure. The blood pressure in the capillaries is influenced by the general arterial pressure, the venous pressure, and the local state of the capillaries. The effect of the venous pressure is more intimately felt than that of the arterial, but when the capillary pressure varies independently of the systemic blood pressure, the chamber pressure follows it preferentially. The capillary pressure is largely independently controlled by (1) a capillariomotor nervous mechanism, and (2) complex physico-chemical influences locally determined or hormonal.

The capillary mechanism helps to account for low intra-ocular pressure in cases of high blood pressure, and high intra-ocular pressure in low blood pressure (e.g., after amyl nitrite). Light causes a fall in intra-ocular pressure due to capillary constriction, this is independent of the iris movement as a rise occurs in the dark-adapted eye when under the influence of pilocarpine [vide glaucoma section].

Axon reflexes.—Those mediated by the fifth nerve, sensory or noxious stimuli produce a histamine response and rise in pressure due to dilatation of the capillary bed.

Reactive response to capillary dilatation.—As dilatation of capillaries increases their permeability, an initial rise in intra-ocular volume pressure due to the former is followed by a secondary rise due to the formation of a plasmoid aqueous with its increased equilibrium level. Such a reaction is studied after paracentesis of the normal eye, and the eye treated with atropine, pilocarpine and adrenaline, respectively. Immediately after the evacuation fall, there is a rapid rise due to capillary dilatation, then a fall, but not to normal level, then a prolonged rise due to the effect of the plasmoid aqueous. After atropine these are exaggerated especially the late rise; after pilocarpine the late rise is flattened out; after adrenaline both the rises are present but much less than in the curve of the normal eye.

Variation with the colloid pressure.—Since the aqueous and plasma crystalloids are freely permeable, differences in osmotic pressure between these two fluids can only be altered for any length of time by varying the relative concentrations of their colloid contents. Experimentally a relative decrease in blood colloids is followed by a rise in the intra-ocular pressure, but clinically, as the colloid content of the plasma is relatively stable, the converse is the usual condition met with, where the colloid content of the aqueous is raised (e.g., inflammations), and the intra-ocular pressure rises.

Volume pressure.—The globe being almost rigid alteration of the volume of any of its contents alters the intra-ocular pressure, e.g., a rise due to dilatation of the capillary bed, or a fall after massage due to diminished aqueous volume. Injection of anisotonic solutions into the blood stream act independently of the general blood pressure, e.g., injection of a hypertonic solution drops the intra-ocular pressure and injection of a hypotonic solution raises it.

The vitreous and lens.—Small changes in volume of the former are important as it occupies four-fifths of the globe. Experimentally increase of alkalinity makes the vitreous gel swell, and increase of acidity makes it shrink. Work *in vivo* in this connection has been inconclusive, but changes in turgidity can occur, and

it is probably a more important field of enquiry than the author indicated in the first edition of this work. It is almost certain that alterations in the volume of the vitreous, brought on presumably by changes in its metabolism and oxidative capacity, do occur and do profoundly influence the intra-ocular pressure. [It is satisfactory to note this attitude towards the vitreous on the part of the distinguished author inasmuch as it means the application of his exceptional gift for research to an aspect of the glaucoma problem which by its insistence has intrigued but frustrated Indian workers for years.] The writer's posterior segment clinical type of glaucoma is referred to.

The compensatory mechanism.—Normally changes in volume pressure are accommodated by the expulsion of aqueous at the angle. Great increases of swelling in the posterior segment abolish this mechanism as the angle becomes blocked. The pressure in the vitreous exits rises, the feeding arteries pile up pressure to maintain the circulation, until the circulation is maintained at practically arterial level.

Chapter V dealing with the effect of drugs upon the eye is new and important.

The autonomic nervous system does not act on involuntary muscle directly but in the case of the para-sympathetic by liberation of acetyl-choline, and in the case of the sympathetic by liberation of adrenaline at the myo-neural junctions. The skeletal muscles of animals lower than mammals are similarly activated, as also those of the mammalian embryo before the nerves have grown out. In adult mammals this response is superseded by a more efficient nervous mechanism (although if the nerve supply is cut and the nerve allowed to degenerate the primitive type of contraction occurs again), with the exception of the extrinsic muscles of the eye which still contract under the influence of acetyl-choline. The peripheral vaso-motor system is largely controlled by the anti-dromic activity of the sensory nerves which is affected through the liberation of histamine. Acetyl-choline dilates the capillaries on intravenous injection, causing a fall in general blood pressure (unless preceded by atropine, in which case a constrictor effect is produced). In small doses it lowers the intra-ocular pressure which follows the general blood pressure, just as small doses of adrenaline or pituitrin, producing vaso-constriction, cause a rise in intra-ocular pressure. The local events in the eye tending to be overshadowed by the effect on the general circulation. Large doses however of acetyl-choline produce contraction of the extra-ocular muscles which causes a sudden rise in blood pressure. This peculiar action on the extra-ocular muscles, alone amongst the voluntary muscles, it shares with nicotine. Acetyl-choline produces a contraction of the intra-ocular muscles, and stimulation of the third nerve acts through its production. The stimulus of bright light acts similarly. Acetyl-choline formed thus is almost immediately destroyed, but if eserine is administered before stimulating the third nerve or exposing the eye to a bright light, it protects or enhances the action of acetyl-choline. Eserine does not produce acetyl-choline nor does it stimulate the myo-neural junctions of the fifth nerve, but activates the already formed substance. If the oculo-motor is sectioned, or atropine is instilled, eserine is ineffective, not because atropine paralyzes the autonomic nerve endings but because it inactivates acetyl-choline, so that though the third nerve is stimulated acetyl-choline is inactivated as soon as produced and no contraction occurs; eserine under these circumstances has nothing to activate as the atropine has preferential effect. Direct stimulation of the third nerve or the muscle fibres overcomes this action of atropine, hence only drugs which act directly on muscle fibres themselves, such as the ergot-derivatives or histamine (so-called amino-glaucozan), can overcome the mydriasis of atropine. Atropine acts by inhibiting the action of acetyl-choline which normally contracts the sphincter. There is then a

contraction of the dilator by reciprocal innervation, but atropine does not stimulate the dilator, since either electrical or pharmacological stimulation of the sympathetic, central or peripheral, causes a further dilatation of the pupil already dilated to an apparent maximum by full atropinization. Also owing to this reaction a pupil dilated with atropine contracts slightly during sleep or narcosis when psychic and sensory stimuli are abolished, the moiety of dilatation due to these influences being removed. Atropine dilates the intra-ocular capillaries, increases their permeability, and causes engorgement of the ciliary region. Thus and also by mechanical interference with the angle it raises intra-ocular pressure.

Eserine is contrary to atropine in its activities. Its action on acetyl-choline has been noted. If the third nerve is sectioned it is ineffective as the tone exercised by the sympathetic over the dilator prevails in the absence of central oculo-motor impulses. In the normal eye eserine produces a rise in intra-ocular pressure partly by capillary dilatation and partly by increasing the tonicity of the recti (experimental animals). In glaucoma however the freeing of blocked drainage produces a fall.

Pilocarpine has a weaker and shorter effect than eserine, but its action is different. Like acetyl-choline it stimulates the muscle itself. When its effect wears off the sphincter shows signs of a para-sympathetic paresis (mydriasis), the opposite of the increased excitability and spasmodic contraction which is a late result after eserine.

Adrenaline produces mydriasis when injected intra-venously in very small doses. When instilled into the conjunctival sac in normal persons no mydriasis ensues, but if the sympathetic is hyper-irritable (Graves' disease, pancreatic insufficiency, section of pre-ganglionic sympathetic or removal of cervical ganglion), the excitability of the end apparatus is augmented and the drug becomes effective.

Similarly when sympathetic effectivity is augmented by cocaine, adrenaline produces marked mydriasis. When the sympathetic is thrown out of action (as by nicotine or ergotoxin), the irritability of the para-sympathetic is raised so that adrenaline contracts the sphincter (the 'inverse action' of adrenaline).

The action on the intra-ocular pressure is of considerable importance clinically in connection with glaucoma. Experimentally (1) very small doses (0.1 c.c. of a 1 in 10,000 dilution) raise the blood pressure and the intra-ocular pressure passively with it.

(2) Large doses (0.1 c.c. of 1 in 1,000 dilution) cause a rise in the blood pressure with an initial fall in intra-ocular pressure due to a definite vaso-constriction in the eye itself, followed later by a rise due to the breaking down of the relatively feeble barrier of arteriolar constriction in the eye itself.

Apart from the general blood pressure the action of adrenaline on the eye is fourfold:

1. In small doses it dilates the capillaries and raises the intra-ocular pressure.
2. In large doses it constricts the arterioles and capillaries and lowers the intra-ocular pressure.
3. In any dose it constricts the plain muscle of the orbit and raises the intra-ocular pressure.
4. It dilates the pupil, an action without significance on the intra-ocular pressure.

In man the action on Müller's muscle is negligible. Clinically it must be remembered that after the capillaries in the eye dilated by a histamine-like substance they are in a refractory phase, resistant to the constrictive effect of adrenaline.

Pituitrin constricts arterioles and capillaries, but like adrenaline this action is less marked in the eye than elsewhere and the raised blood pressure tends to break through the barrier offered by the eye arterioles.

Cocaine produces sub-maximal mydriasis and is overcome by stimulation of the para-sympathetic or the action of light. Cocaine acts as a stimulant to those tissues where the sympathetic is motor, and as

a depressant where it is inhibitory. Its action in constricting the conjunctival vessels and dilating the pupil is in the first category. The action is excitatory to sympathetic influences. [Its action towards adrenaline might be likened to that of eserine towards acetyl-choline].

Ergotamine produces mydriasis in man, but miosis in the cat.

Histamine acts directly on the sphincter muscle and contracts the pupil. It constricts arterioles and dilates the capillaries increasing their permeability to the maximum; if the capillaries are normal in tone their dilatation results in a rise in intra-ocular pressure, if they are atonic and fully dilated already the drug causes a fall by constricting the arterioles. The miotic effect is also effective in glaucoma.

Nicotine is irregular in its action on the autonomic system, depending on whether its action is most powerful on the superior cervical ganglion (sympathetic), or ciliary ganglion (para-sympathetic).

Chapter XII on glaucoma should be read in conjunction with part I of the book. The subject-matter is the same as in the previous edition, but a few points may be touched upon.

Variation in the vitreous gel is a most important factor in determining volume pressure; this has been alluded to in chapter IV, but the reaction of the blood does not appear to exert a controlling influence here. This is an aspect of volume pressure which needs thorough investigation.

The various causes of increased intra-ocular pressure discussed above (*i.e.*, glaucoma) have been frequently promoted by individual workers regardless of perspective. The author says 'The adoption of such a position is quite unphilosophical' and shows a disregard for 'the composite nature of the problem'. Perhaps the fairest assessment of the position.....is to state that an increased intra-ocular pressure may be due to one of two main causes:—

- (1) a dilatation of the capillaries 'with all that this entails'; and
- (2) 'an increase in the turgidity pressure of the vitreous and of the lens'.

Diagnosis.—The value of Troncoso's gonioscope is mentioned in observing conditions at the angle. Thiel's test with sodium fluorescein for determining increased permeability of the capillaries, which is said to be valuable in the early stages, still requires clinical confirmation. Deviations from the normal variations of the intra-ocular pressure are important in diagnosis, *e.g.*, binocular dissimilarity, the effect of decubitus, massage [homatropine], also deviations from the diurnal variation or the variations during dark adaptation, when estimated by careful and strictly comparable tonometric observations. The light sense in diagnosis (Derby) suggests that delay in dark adaptation and dulling of sensitivity to dim light form a syndrome of value. [Clinically this presents practical difficulties.]

Under the heading of treatment there are no new suggestions. That ergotamine produces miosis and a fall in tension, and can be administered *per os* over a prolonged time, is noteworthy. [Further experience with this drug is desirable.]

[The fact that it is possible to carry out prophylactic treatment in the glaucoma of epidemic dropsy has escaped the author's attention. That glaucoma is a symptom-complex of a disease which appears in epidemic-like outbreaks, and that alone in epidemic dropsy glaucoma appears to result from ætiological factors productive of a disease entity, is an old Indian observation which does not seem to have stirred the interests of research workers on this subject in Europe or America.]

PART II

Intra-ocular infections.—Excluding infections introduced through wounds or ulcers, there is a large group of intra-ocular inflammations where the ætiology is

obscure, and if organismal, is a blood stream infection. In a small number of these there may be definite invasion by the tubercle bacillus, *T. pallida*, or the gonococcus. Common pyogenic organisms may reach the eye in this way, but if so usually set up panophthalmitis. In the vast bulk of the uveal inflammations the presence of an organism in the globe has not been proven, although such lesions are usually attributed to tubercle, syphilis, gonorrhœa, or infection transferred from a septic focus elsewhere in the body. A certain amount of unconvincing bacteriological work has been done in this connection, in which investigators have tried to prove that certain organisms are responsible. It has never been shown that, from the uveal tissues of this great group of inflammations, organisms can be regularly isolated; in fact such isolations (or demonstrations *in situ*) are rare (except in the case of syphilitic keratitis). In spite of this it is customary for ophthalmologists to speak freely, if incorrectly, of tuberculous, syphilitic, septic infections, etc. Different countries and schools have their fashions in this respect. The same type of uveal lesions may be tuberculous in Germany, syphilitic in France, and due to focal sepsis in England. The protagonists of such varying aetiology usually base their belief on the results of treatment. The author considers focal infection as established, in spite of want of proof, but points out that the eye response may be:

1. Direct organismal infection.
2. Systemic intoxication.
3. Allergic sensitization.

He discusses the theory of elective localization which is analogically likely, but not proven. He considers the possibility established that an organism or its toxin can produce sensitization of the eye tissue and hence recurrent inflammatory responses under minimal activating doses. [To accept some of the allergic hypotheses it would seem necessary to assume that the eye is more prone to allergic phenomena than other highly organized tissues.] Hypotheses in this field however attractive are very unconvincing and treatment is largely by trial and error. Specific immunity methods have been largely replaced by generic protein shock tactics. The chapter leaves us with a feeling of humiliation and a certainty that our efforts at treatment in this field are largely empirical.

The ocular pigment and intra-ocular tumours.—The recent conceptions of the origin of melanin have helped to clarify our views. It would seem that the colourless mother substance of melanin (melanogen),—probably identical with 'dopa'—is, like the latter, changed into melanin by those cells of pigmented regions which possess the specific intra-cellular oxidase; the mother substance being brought to such cells by the blood stream. It is possible that melanin and adrenaline are derived from the same precursors and form alternative end-products of metabolism. If the deranged adrenals do not manufacture adrenaline more melanogen is available and appears as pigment (Addison's disease). If the cells containing the specific oxidase proliferate a localized melanoma or general melanomatosis may result. An absence of enzyme may mean albinism. The cells which exercise this chromogenic function, in so far as the skin is concerned, are the basal cells of the epidermis. Other views are held, but there is much to support the idea that these are the true melanoblasts. Pigment formed in them may migrate to the connective tissue cells of the corium and there be phagocytosed, or carried by the mesoblastic cells which thus act as melanophores or chromatophores. But the only cases in which connective tissue cells or endothelial cells give a positive 'dopa reaction' are those of tumours where the amount of melanogen is enormously increased. So far as the skin is concerned therefore the evidence points to the preponderant rôle of the basal cell layer in pigment production.

In the eye, conditions are different. The retina represents the epithelium and theoretically the choroid

ought to derive its pigment from the retinal chromatoblasts, its own cells merely functioning as chromatophores. There is evidence to show that this is not so. Before pigment appears in the embryonic choroid, oxidizing ferment is present, and they give a positive 'dopa reaction'; the normal mesodermal cells may contain even the colourless mother substance. In the eye at least melanogenesis is a function of both epiblast and mesoblast, and although ordinarily the bulk of melanogenesis is a function of the basal layer cells of the epidermis, there is no reason to think that it is an absolute hard and fast rule. In abnormal states mesodermal cells other than those of the eye may contain the oxidase. The subject is not quite so simple as it seems at first sight, and the adrenaline melanogenic alternative function of the adrenals leads up to many speculative ideas regarding the reaction of black and white experimental animals, relative hypo-adrenia in melanosis, etc. For practical purposes we may take it that as far as the eye is concerned pigmentation may be ectodermal or mesodermal and the malignant melanoses either carcinomata or sarcomata.

The treatment of ocular neoplasms by radiant energy.—The treatment of ocular neoplasms by radiant energy has become more practicable with improved technique in the use of radium. Increasing experience has enabled dosage to be determined. In treatment only the gamma rays are useful, the alpha rays are indifferent, and the burn-producing beta particles may all be eliminated by a platinum screen of 0.8 mm. thickness. A technique for intra-ocular neoplasms has been elaborated using radon seeds either on the surface of the globe or actually planted in the intra-ocular growth. Treatment of glioma seems more promising than that of sarcoma but both are in the experimental stage. Experience with the epibulbar neoplasms has been extensive and the use of radium for such growths has been well reported on. A small series of treatments using a metal holder is recorded. [No mention is made of paraffin shell holders, a simple and more generally applicable method.]

Trachoma.—The author pertinently opens chapter VIII with a reference to the accurate clinical diagnosis of trachoma and the bearing of this essential point on aetiological research. Wilson's biomicroscopic work in this respect is reviewed. The cicatricial changes of the lid and the corneal changes are dealt with. The Prowazek-Halberstæder bodies are considered of doubtful diagnostic value and of still more doubtful aetiological significance. [This is borne out by still more recent work than that referred to in the text.]

The communicability of the disease is regarded as proven, but the bacterial origin put forward by Noguchi has not been upheld by recent work on *B. granulosis*. The case for a filterable virus has little evidence so far to support it. The position may be summed up by saying that the aetiology of trachoma is not clear but is clearing. It would seem that no recent treatment has appeared which is better than the older methods.

The cornea.—The chemical constitution, nutrition, and respiration of the cornea open chapter IX. It is shown that an alkaline medium is most favourable for the transcorneal transference of the ordinary drugs, except pilocarpine. Under epithelial dystrophy, Gifford's observations alone are mentioned, which hardly does justice to this field of work.

Herpes of the cornea.—Under this heading much old ground is covered, nothing new is brought forward, and the subject-matter is open to considerable criticism to-day. To those interested in virus disease, there are obvious flaws, but of course the author is not responsible for the confusing terms or confusing statements used, such as 'herpes zoster ophthalmicus' is met with in two forms, epidemic herpes zoster and symptomatic herpes zoster. Apart from the obvious objection to the use of the term zoster in this connection, it is difficult to follow what exactly herpes

zoster epidemicus means, and those accustomed to see large numbers of cases of sporadic herpes ophthalmicus will hardly regard the illustration as suggestive of the corneal lesions in this affection. One is left wondering what exactly herpes zoster epidemicus is. Indian workers will notice the resemblance the illustration bears to certain cases of epidemic punctate keratitis. Herpes ophthalmicus may be due to filterable virus, but the identity of this virus with that of varicella or any other known virus is at present not proven. The author accepts the view that the virus of herpes simplex (labialis, facialis, genitalis, cornealis), also known as *H. febrilis*, may produce encephalitis in experimental animals, but the remainder of the work in this connection he admits is open to doubt.

Treatment of corneal ulcers by ultra-violet light.—The abiotic action of short-waved light upon the eye was dealt with in the previous edition. For practical purposes only rays below 3,000 Å. U. may be considered active, and then when used at a certain intensity (200,000 erg-seconds per square centimetre). When used within these limits an abiotic reaction is produced in the cornea after a latent period of 6 to 8 hours. The actinic rays are absorbed into the protein molecule and produce photo-chemical denaturation changes demonstrable histologically as an acidophil degeneration. The histological changes in the epithelium have been studied in detail by the author. It will be remembered that the response includes shedding of epithelium, vascularization, and the production of an inclusion-body-like change in the cell protoplasm. The reaction produces photophthalmia. Clinically we may have :—

1. Industrial photophthalmia.
2. Solar photophthalmia (snow blindness).
3. Chronic photophthalmia (continued short exposures in certain industrial workers).

The corneal cells are injured by small intensities and killed by greater intensities of radiation, the pathological change decreasing with the depth. Therapeutically the greater reaction is most useful (under proper control), in inflammatory ulcerative and degenerative corneal conditions. The good effect depends on killing the superficial cells and the organisms, the vascular reaction with invasion of the cornea, the stimulation to rapid repair of the epithelium, and possibly immunological processes stimulated by the absorption of products of cell disintegration.

In the application of treatment great care is necessary. The employment of sensitization to enable light of longer wave-length and greater penetration to be used is not satisfactory and may be dangerous. The author's technique of radiation is given and his ophthalmic radiation lamp described and figured. In hypopyon ulcers, chronic ulcers (with deep changes), recurrent ulcers, phlyctenular ulcers, and tuberculous keratitis good results may be expected. The dose is determined by first finding out that which produces a minimal erythema of the individual's skin, and regulating that for the eye in conformity therewith. The dose required to excite an abiotic lesion of the cornea being slightly less than that which produces a minimal skin erythema.

Corneal tattooing.—The desirability of depositing the stain without producing a fibrous tissue response is noted. This is so with all methods in use, no new ideas are put forward.

Keratoplasty.—Corneal grafting has recently been given an extravagantly prominent place in England both in the medical and in the popular pictorial press, on account of a limited measure of success following on the experimental work of Thomas. As the Indian lay press has blindly followed suit the author's assessment of the position at its proper value is welcome. The practical application of Thomas's experimental work to the relief of human blindness in a few cases is hardly comparable with the notable clinical successes

achieved by Elschning in a relatively large number of cases some years ago. The subject is discussed under three heads :—

1. Total keratoplasty.
2. Superficial lamellar keratoplasty.
3. Penetrating circumscribed keratoplasty.

The author dismisses the first (perhaps somewhat prematurely) as impracticable. The third certainly seems to be the method of choice. Full technical details are given. It is interesting that in interstitial keratitis the chances of success are better than in other types of corneal opacities. In such cases too, while the graft sometimes becomes opaque, the surrounding cornea clears up. [There are no real difficulties in the performance of human homotransplantation. Even existing anterior synechiae may be broken down and a successful graft accomplished, but end-results are never certain.]

Corneal contact glasses.—Introduction of ground contact glasses which can be manufactured in series has greatly advanced their practical utility, so that now it is possible to prescribe them for the correction of refractive errors. In irregular astigmatism and conical cornea, they provide a valuable method of improving vision capable of utilization by the average ophthalmologist. A practical difficulty is the expense of standard sets and of the prescribed glasses themselves. In prescribing contact glasses two separate considerations must be borne in mind :

- (1) The fitting of the scleral rim.
- (2) The optical correction.

The first is most important, as a good fit is essential to comfort without which the glass cannot be worn. The optical correction is dependent on the refraction of the eye and the corneal radius of curvature. The latter may be measured by the ophthalmometer. Knowing these it is relatively easy to ascertain the best correcting glass and the additional refractive power required for incorporation in the curvature of the glass. The method has not as yet found very general use, but has obvious advantages in certain cases, and those expert in prescribing them have proved their practical value. Their use for optical purposes must not be lost sight of by the average ophthalmologist. Apart from this, they have proved useful in protecting the cornea, treatment of corneal ulcers, plastic operations on the cornea, and relieving photophobia and spasm.

Detachment of the retina.—As might be expected the chapter on detachment of the retina is extensive. The method which Gonnin introduced a relatively short time ago has been arduously studied and improved upon by many workers. The author points out that it is an error to predicate a common mechanism in the production of detachment. Aetiological factors are discussed and the author shows that the evidence available points to the conclusion that there are two main classes of retinal detachment :—

1. The exudative type associated with inflammatory disturbances of the choroid, etc., in which the retro-retinal fluid is albuminous (at least until a hole occurs).
2. A non-exudative type in which, whatever determines the hole, the immediate cause of the detachment is the formation of a hole. There is no detachment till the hole occurs and the retro-retinal fluid is vitreous (more or less degenerated).

He does not include all detachments in these groups, but the bulk of so-called idiopathic cases. The essential aetiological factor in both is a preceding degeneration or inflammation which renders possible their occurrence although, in the case of 2, this factor may be trivial and unnoticeable till the tear and the detachment suddenly supervene. The Moorfields statistics are quoted in support of the classification of holes and

their site of occurrence. It appears that the relative frequency of the various types is:—

Round	34 per cent
Dialysis	31 "
Arrow-head	25 "
Slit	5.5 "
Irregular	4.5 "

Peripheral dialysis (disinsertion of Gonion) occurs more commonly in hypermetropes and emmetropes and is rare in high myopia. In the others the main incidence is in myopia. The round hole occurs chiefly in the temporal half, the site of election being the superior temporal quadrant, the arrow-head tear in the superior half, chiefly the superior temporal quadrant, while the anterior dialyses are, in the main, in the inferior temporal quadrant.

Treatment.—The modern treatment is discussed fully from Gonin's original conception of closing the hole and his method of doing it, to the later barrage procedures, where neither the hole, nor the elaborate machineries for its localization (the description of which takes up a large part of the chapter), play such an important part. The ground covered is all so familiar to ophthalmologists by reason of its broadcasting in recent current ophthalmological literature that we need only say that it is a very useful summary of the evolution of the modern treatment of detachment. One would like to have seen more than a reference to literature in connection with Walker's technique. The author wisely withholds judgment on any of the modern procedures as they are still in the experimental state, but gives due credit to the extraordinary advance in the treatment of detachment which igni-puncture and the methods evolved therefrom have achieved.

Hæmangiomas of retina.—The author accepts the conception that various types of hæmangiomas of the retina described in ophthalmic literature form part of the syndrome known by the name of Lindau's disease. Lindau's thesis brought the condition into line with two rather similar affections, namely, those of Bourneville and von Recklinghausen. Their resemblance led von d. Hoeve to group the three as phakomatoses. In their abnormal tissue manifestations Lindau's disease is mainly mesodermal, Bourneville's mainly ectodermal, whilst von Recklinghausen's disease is mixed.

Cataract.—In this section there is little change from the previous edition of this work except further details concerning lens metabolism. The decrease of the soluble crystallins and increase of insoluble albumoids with age and in cataract, means a decrease in cysteine, the amino-acid associated with the oxidative activity of the lens. The reducing power of the lens decreases with age or with the maturation of a cataract. But whether this diminution of cysteine is of ætiological significance, or merely an accompanying event in a degenerative process of diverse ætiology, is unknown.

The remainder of the chapter will perhaps prove a little disappointing to Indian readers and illustrations 142 and 144 are hardly suited to a work with such a title. Lacarrère's electrodiaphane is mentioned, but although the idea is not without interest and may bear fruit, it is unlikely that it will be in the extraction of the cataractous lens.

Indian workers will not agree with the statement 'all methods of intra-capsular extraction are difficult'—this is not true of forceps extraction. Many however will agree that the last word has not yet been said on the possible late effects of intra-capsular extraction on the vitreous.

Sympathetic ophthalmitis.—The two surviving theories, the anaphylactic theory and the infective theory, are reviewed in this chapter (chapter XIII). Experimental work supports the former to some extent, but the practical issue of desensitization and immunization with uveal pigment is unsatisfactory. Recent investigation by Woods of a variety of uveitis cases showed that positive intra-dermal pigment tests were found only in those patients in whom there had been a penetrating wound of the eye involving the uveal tract. On the other hand in this series a number of cases showed pigment hypersensitivity without sympathetic disturbance. The deduction is that the development of allergy seems to exercise a predisposing rôle in the ætiology of the disease, but it alone cannot be the single or determinant cause.

Møller's recent support of a tuberculous ætiology is dealt with. His thesis is based on a few cases of isolation of *B. tuberculosis* from the injured eye. His work is not in conformity with the consistently negative results which have been obtained hitherto on the animal inoculation of tissues removed from eyes enucleated for sympathetic disease. If tuberculosis is associated with the affection, the actual bacillary invasion of the eye must constitute only one-half of the story. A second infective possibility is that a filter-passing virus is responsible. This theory does not stand the test of the reproduction of the disease experimentally by infective material. The author finds neither the infective theory nor yet the anaphylactic theory all-sufficing, and, in the absence of other suggestions, considers that the truth may be in a combination, i.e., 'that a developing allergic pigment hypersensitivity predisposes the second eye to other noxious agents, rendering it more liable to infection and determining the characteristic clinical course. What the noxious agent is, or even whether it is always the same or not, is at present unknown'.

Note.—The author's wording is freely quoted, but not always in quotation marks. The reviewer's remarks are for the most part in square brackets.

Medical News

THE PHYSIOLOGICAL SOCIETY OF INDIA

'The Physiological Society of India' was started in Calcutta in July last year, and was registered in December. This society aims at promoting and organizing researches in physiological and biochemical problems of India by enlisting the co-operation of physiologists and biochemists working in the various laboratories of India and also of those scientists and medical men who take an interest in these two basic medical sciences. The society had already arranged four ordinary meetings in which several important contributions by research workers were discussed. The office-bearers of the society are:—

President:—

S. C. Mahalanobis, B.Sc. (Edin.), F.R.S.E., I.E.S. (retd.), Professor of Physiology, the University of Calcutta and Carmichael Medical College, Calcutta.

Vice-Presidents:—

Sir Nilratan Sircar, Kt., M.A., M.D., D.C.L., LL.D., formerly Vice-Chancellor, Calcutta University.
Sir Kedarnath Das, Kt., C.I.E., M.D., F.C.O.G., Principal, Carmichael Medical College, Calcutta.
Sir Upendra Nath Brahmachari, Kt., M.A., M.D., Ph.D., Professor of Tropical Medicine, Carmichael Medical College, Calcutta.

Dr. Bidhan Chandra Roy, M.D. (Cal.), M.R.C.P. (Lond.), F.R.C.S. (Eng.), Professor of Medicine, Carmichael Medical College, Calcutta.
 Dr. H. E. C. Wilson, Professor of Biochemistry, All-India Institute of Hygiene and Public Health.

Secretaries:—

(1) N. C. Bhattacharji, M.A., B.Sc., Professor of Physiology, Presidency College, Calcutta.

(2) N. M. Basu, M.Sc., Professor of Physiology, Presidency College, Calcutta.

*Asst. Secretary:—*Dr. P. N. Brahmachari, M.S.D., M.B., P.R.S.

*Treasurer:—*Dr. B. B. Sarkar, D.Sc. (Edin.), F.R.S.E., Professor of Physiology, University of Calcutta.

The executive committee of the society consists of the above office-bearers and eleven other members representing various institutions.

TROPICAL DISEASES BULLETIN

Tropical Diseases Bulletin, Vol. 31, Supplement, December 1934. 219 pp. 'Medical and Sanitary Reports from British Colonies, Protectorates and Dependencies for the Year 1932' summarized by H. Harold Scott, M.D., F.R.C.P., D.P.H., etc., Assistant Director of the Bureau of Hygiene and Tropical Diseases. [Price 5/-].

THE fourth Supplement to the *Tropical Diseases Bulletin*, published in December 1934, contains summaries by Dr. H. Harold Scott of fifty-five medical and sanitary reports relating to the year 1932 from British colonies, protectorates and dependencies. The summaries follow the same general arrangement as in the three earlier supplements, giving for each country the year's record of vital statistics, maternity and child-welfare work, school hygiene, general sanitation, housing and town planning, etc., followed by particulars of the incidence of diseases such as malaria, enteric fever, leprosy, trypanosomiasis, yellow fever, yaws and syphilis, and the measures taken locally to combat them. Special health campaigns and investigations carried out in the various government laboratories or in the field are also noticed, and a table at the end of the summaries gives in succinct form the vital statistics and other cognate data extracted from the main body of the reports.

The records on the whole show that in spite of retrenchment of medical staffs and curtailment of expenditure on public health services the general health of the English communities has been well maintained and no appreciable increase of sickness has occurred in the native communities in the year under review. Possibly the closing down of some out-stations from which records were formerly available, and the inability of impoverished natives to travel far in search of medical help, may lend a more favourable appearance to the figures for native sickness in 1932 than is warranted by fact. Fortunately this year was comparatively free from major epidemics, and the fear that some native tribes, living at the best of times on a bare subsistence diet, might, as a result of the depression, show a greatly reduced resistance to any serious epidemic outbreak was not realized. Contemplation of the risk has however brought about a more general recognition of the dangers of malnutrition, and of the need for some effort to improve agriculture and husbandry in the interests of native populations. In Nigeria a dietetics committee was set up in 1932 to secure co-operative action by the agricultural, forestry, veterinary, geological and medical departments with a view to improving the quality of the foods eaten by the natives.

Retrenchment has had another result in bringing to the fore the question of the local training of natives for medical duties. Even in normal times the funds available for medical services are inadequate to provide enough qualified Europeans to meet the needs of the general native population. In the Gold Coast for instance there was estimated to be one government

doctor to about 53,000 persons, and this number is now even greater owing to retrenchment of staff. To meet this situation a committee was appointed to draft a scheme for a medical school and as a result a four-year course of training for nurse-dispensers was instituted to qualify natives to take charge of outlying rural dispensaries in the Gold Coast. Elsewhere in the tropics medical schools exist for training native general practitioners, notably at Suva in Fiji where native practitioners have been successfully trained for service in the Western Pacific, and in Uganda where native graduates from the medical school at Mulago now hold responsible posts. Such training however calls for experienced European medical men as teachers, a call the more difficult to meet as retrenchment proceeds, so that there is danger of a vicious circle being set up.

With regard to medical research in the colonies in 1932, the pursuance of the policy of retrenchment seems to have created an atmosphere of uncertainty as to the future, and with few exceptions the staffs of research laboratories have shown little inclination to embark on any long-term schemes of research, confining their activities for the most part to a continuance of work begun in previous years or to the solution of problems arising either in the course of routine laboratory work or in the clinical work of the hospitals.

For all interested in the medical problems of the Colonial Empire Dr. Scott's summaries of the medical and sanitary reports year by year provide a fund of information and much food for thought.

THE INDIAN HONOURS LIST

1st January, 1935

THE following are the names of medical workers in the Indian Honours List of date 1st January, 1935. We offer them our congratulations:

Knighthood

Lieutenant-Colonel J. N. Duggan of Grant Medical College, Bombay.

C. I. E.

Lieutenant-Colonel E. S. Phipson, Medical Officer, European General Hospital, Aden.

Major H. J. Rice, Indian Military Hospital, Poona.

O. B. E.

Major Ahmad Khan Sahibzada, Civil Surgeon, Hazara.

M. B. E.

Mr. Abdulqadir Khan, lately Civil Surgeon and Superintendent, Kohat Jail, North West Frontier Province.

Kaiser-i-Hind Medal

First Class

Mr. G. O. Teichmann, Medical Missionary of Baptist Mission, Chandraghona, Chittagong Hill Tracts, Bengal.

Kaiser-i-Hind Medal

Second Class

Miss M. E. Franklin, lately in charge of Women's Hospital, Rawalpindi.

Miss N. Sharpe, Darbhanga Hospital.

Miss J. F. Smith, Darbhanga Hospital.

Miss A. Whitcombe, Red Cross Society, Poona.

Kaiser-i-Hind Medal

Third Class

Mr. G. K. Karanjai, Medical Officer, Rajshahi, Bengal.

Rao Bahadur

Kizhakkekallathil Keman Nayar Avargal, Assistant Superintendent and Second Ophthalmic Surgeon, Government Ophthalmic Hospital, Madras.

Sardar Sahib

Jemadar Jasmer Singh Gill, Sub-Assistant Surgeon, His Excellency the Viceroy's Dispensary.

Khan Sahib

Sayyad Riaz Ali Shah, District Medical Officer of Health, Punjab.

Munshi Muhammad Rahim, Medical Practitioner of Hangu, N. W. F. P.

Munshi Saeed Ahmed, Civil Assistant Surgeon-in-charge, Civil Hospital, Mansahra, Hazara District.

Mr. Mohammed Noorul Haque, Sub-Assistant Surgeon, East Indian Railway, Allahabad.

Rai Sahib

Mr. Srish Chandra Sarkar, Assistant Medical Officer, Deol Jail.

Amin Chand, Baluchistan Civil Medical Department, Sub-Assistant Surgeon, Baluchistan.

Jemadar Gajraj Singh Gorkha, Indian Medical Department, Sub-Assistant Surgeon, Legation Hospital, Nepal.

Rao Sahib

Panangadam Manakatan Sridharan Avargal, Sub-Assistant Surgeon, Madras Presidency.

Mr. Trichinopoly Doraiswami Rajoo, Assistant Medical Officer, King Edward Memorial Hospital, Secunderabad.

UNIVERSITY OF LUCKNOW

We draw the attention of our readers to an advertisement in this issue for a Professor of Obstetrics and Gynaecology at the above University. We have also been asked to inform any candidates who are members of the Indian Medical Service that their applications should go through the office of the Director-General, New Delhi.

Current Topics

Coccus Infection of the Kidney: Its Rôle in the Formation and Recurrence of Stone

By HARRY A. FOWLER, M.D.

(From the *Urologic and Cutaneous Review*, Vol. XXXVIII, August 1934, p. 594)

AMONG the lesions of the upper urinary tract requiring in many cases surgical interference for its relief calculous disease is easily the most frequent, and for that very reason certainly the most important.

During the past few years progress in dealing with this problem has been made chiefly along two lines: First, the development of an operative technique which insures greater certainty in the complete removal of all the stones, together with the least damage to the structure and function of the kidney by the necessary surgical attack. During this period one notes a marked tendency toward conservatism in the management of these cases. Pyelotomy or pelvolithotomy for stone in the kidney has found an increasingly wider application and to that extent has supplanted the less conservative operation of nephrolithotomy. Resection is now successfully practised in favourable cases with the preservation of healthy kidney tissue formerly sacrificed by nephrectomy. In many cases ureteral calculi which were formerly treated by ureterolithotomy are now made to pass to the bladder by intra-ureteral manipulation, thanks to the development of these ingenious methods of modern urology.

Second, in the study of etiology. Despite the intensive study of this subject during the past ten years, the exact etiology of stone formation is still unknown. The problem remains unsolved, although important additions to our knowledge have been made. In the light of our present knowledge it is difficult to escape the conclusion that fundamentally the formation of an aseptic stone in the kidney results from a disturbance in the colloid-crystalloid balance which holds the stone-forming constituents of the urine in solution, and that this disturbance, whatever its character, occurs at the kidney level. What brings about this imbalance, what precipitates or initiates the process we do not know. Apparently this protective mechanism of the kidney is finely adjusted to the demands made upon it under normal conditions and admirably serves its important purpose under an extraordinary variety of conditions of health and disease since the vast majority of humans never suffer from calculous disease. However, one observes many patients otherwise in apparently good health who exhibit a tendency to the formation of aseptic stone

in the kidney for which no adequate explanation can be found. In these cases the affection is usually unilateral, rarely bilateral, which suggests that the ultimate cause whatever it may be is local in character.

Certain dietary irregularities have long been thought to play an important part in their development, although there was little or no experimental basis for such a theory. Recently, however, it has been shown that experimental animals, fed upon a diet deficient in certain vitamins (vitamin A), develop calculi in the urinary tract. To what extent, if any, this dietary deficiency theory is applicable to man has not been definitely shown.

Nutritional disorders producing disturbances in calcium metabolism, whereby its excretion by the kidneys is markedly increased, has been suggested as a factor in stone formation. This has been observed particularly in certain non-suppurative bone lesions, fractures, etc. The association of calcium deposits in the kidney with hyperparathyroidism has recently been brought to our attention and is supposed to be the result of disturbed calcium metabolism. These newer studies are exceedingly interesting and stimulate a renewed interest in the study of the perplexing problem of etiology of stone.

Among the secondary factors of greatest importance and about which there is general agreement are stasis due to obstruction and infection. Obstruction to the free escape of urine from the kidneys with its attendant stasis favours the retention and further growth of minute calculi. Once the mechanism of stone formation is set in motion, stasis is probably the most important single factor favouring continuance of the process. That it does not initiate the process, however, is abundantly clear from the fact that varying degrees of dilatation of the upper urinary tract are frequently observed clinically without accompanying calculous formation.

Infection is decidedly the most important complication of upper urinary tract lithiasis. With its advent the clinical picture is completely changed. It causes a more rapid destruction of kidney tissue; its persistence leads to inevitable destruction of kidney function and when bilateral to ultimate death of the patient in uræmia. Its importance as a complication is recognized in the present-day standards of treatment which require, among other things, not only the removal of all stones but the clearing up or eradication of all infections, local and focal, and the preservation of kidney function by providing adequate drainage.

The treatment of infection when present and its prevention in aseptic cases, therefore, becomes of

equal or even more importance than the removal of the stone. The study of the character of infection in a given case may and often does determine the nature of the operation to be performed.

Important, therefore, as a complication of renal lithiasis, infection as a factor in the formation and recurrence of kidney calculi is perhaps still more important. And it is in our knowledge of this relation that the greatest progress has been made in recent years.

Of the two types of renal infection, bacillary and coccid, the older statistical studies showed a great preponderance of the former; and *B. coli* is usually considered the most frequent organism occurring in upper urinary tract infections. Analyses made by recent observers, however, indicate that this preponderance is due to the greater frequency of this type of infection in the female, both children and adults. In the male sex coccus infection is proportionately much greater and equals or even exceeds that due to the bacillary type. In certain clinics with a male clientele bacteriological investigation shows a preponderance of the coccus over the bacillus type in urinary tract infections.

The natural history of coccus infections of the kidney is now fairly well understood. Since the discovery of these organisms by Ogsten in 1881 and the early studies a few years later by Albarran of the characteristic renal lesions produced by them, the whole problem has been thoroughly explored until now one may say that, with the possible exception of the tubercle bacillus, it is the best understood type of renal infection as to etiology, manner of invasion and lesions produced. Two distinct clinical groups of cases are now recognized—the acute and the chronic.

In the acute type of infection the patients succumb early to an overwhelming toxæmia unless promptly relieved by nephrectomy. Less fulminating cases are now recognized which yield to more conservative treatment. Finally, what seems to me a most important contribution to the subject was recently made. Attention was called particularly to the frequency of mild types of the infection which are frequently overlooked by reason of the difficulty in diagnosis. This is a possible sequential relationship between these acute infections with pus-producing cocci and the much more chronic infections believed to be caused by the colon bacillus group. In several cases an early pure coccus infection was succeeded by a mixture with colon bacilli. These infections usually occur as a complication of upper respiratory tract infections, septic wounds, and various cutaneous infections to which the symptoms are usually ascribed. The diagnosis is based upon mild fever, loin tenderness and pain, coupled with the demonstration of cocci in large numbers in the urine. The urine often shows little or no evidence of infection and may appear perfectly normal. The presence of infection in the urine is demonstrated by direct smear as follows: A specimen obtained with the usual precautions, second glass voided specimen in the male, catheterized bladder specimen in the female, is placed in a centrifuge tube and spun at high speed for several minutes. It is then decanted and the sediment mixed with the last few drops at the bottom of the tube is used for making direct smears on a slide. These are dried and stained with methylene blue and Gram stain. This method of demonstrating the presence of infection is both accurate and dependable and serves admirably for all clinical purposes.

CHRONIC TYPE

A very interesting discussion of staphylococcus disease is to be found in a series of papers by Ryle and by Joyce published in *Guy's Hospital Reports* (Vol. 80, April 1930). Ryle points out that, 'while staphylococcus infection most frequently remains confined to the skin in the shape of boils or a

carbuncle, it may lead to a bacteriæmia or a septiciæmia and thus to a group of sequelæ so varied that staphylococcus fever may well be regarded as one of the most protean of infective diseases—and in common with typhoid and pneumonia as a specific fever'. Blood stream infection from the superficial focal infection occurring as a complication at times takes a benign form (bacteriæmia) with a single 'fixation' abscess or several small abscesses or a severe form (septicæmia) with multiple metastases and the clinical picture of a blood stream infection. According to Joyce, the deeper structures most commonly involved are the bones, especially in children, osteomyelitis, while in adults infection of the kidneys is the most important complication. During a period of ten years 61 cases of severe staphylococcus disease were studied in 14 of which renal lesions occurred. These were, for the most part, suppurative lesions of the cortex with extension to the perinephritic tissues. In four cases the process ran a protracted chronic course resulting in complete destruction of the kidneys. It is noted that in three of these the infection was associated with a phosphatic calculus, while in the fourth the presence of a stone is suggested by the clinical findings, although a complete urologic study had not been made at the time of the report (case No. 11). These papers are important in calling attention to the specific character of staphylococcus fever as a distinct clinical entity with a definite demonstrable etiology in most cases. The danger of blood stream infection as a complication of cutaneous suppurative lesions with widely spread metastases is clearly shown. In the chronic forms of the disease when involvement of the kidney occurred, stone formation was common. It is with this association of stone and coccus infection that we are now primarily concerned.

RELATION OF COCCUS INFECTION TO STONE FORMATION

The literature on the subject discloses a wide divergence of views concerning the relation of coccus infection to stone formation. During recent years and largely as a result of clinical observation the important rôle of this type of infection in the formation and particularly the recurrence of upper tract lithiasis has been recognized. An extensive review of the whole subject was made by Hellström and published in 1924. This report has not received the attention its importance deserves. Of 13 cases of chronic staphylococcus infection, calculous disease of the kidney and ureter occurred in nine. This led to a study of the composition and structure of these calculi. It was found that the inorganic material was invariably composed of amorphous calcium phosphates, carbonates and triple phosphates. By dissolving out the inorganic constituents of a small stone with hydrochloric acid the organic material remained as a gelatinous mass which was spread upon a slide and stained. This was shown to consist of a mass of staphylococci. In order to study the relation and distribution of this organic material small stones were embedded, decalcified and sectioned. By this technic it was found that the nucleus was composed of a mass of staphylococci and that the body consisted of layers of these organisms alternating with the inorganic material.

Hrynshak found staphylococci in a stone associated with a bacillus infection of the urine. The specific character of the stone was thus identified and at the time of its formation a pure staphylococcuria must have been present. The logical explanation for the bacilluria is that these organisms were secondary invaders entirely supplanting the staphylococcus which, at the time of the observation, had completely disappeared from the urine. This observation, therefore, confirms the view of many who believe that, in mixed infections of *B. coli* and staphylococci, the latter is the original invader while the colon bacillus is a secondary intruder and the tendency is in such cases for the staphylococcus to disappear gradually, leaving the colon bacilli, as Cabot expresses it, 'in full

possession of the field'. This view is strongly supported by Hellström who states, quoting Faltin, that this observation was first made by English workers and reported as early as 1898 at a meeting in Edinburgh. The observations of Cabot and Nesbit already referred to lends support to this view.

Another question of great practical interest is whether staphylococci are ever secondary invaders. Does a kidney, once infected or subject to repeated bacillary infection, ever become secondarily infected with organisms belonging to the coccus group? The reaction of the urine and the infecting organism at the time of the original renal infection are given, as well as the same data at the time of recurrence of infection and demonstration of a stone in the upper urinary tract. The composition of the stone removed at operation in each case is also given. Complete data of this kind are as valuable and informative as they are rare in such reports. Of interest in the present connection is the fact that in 16 cases the urine was acid and colon bacilli were present during the first attack, in nine of which the urine subsequently became alkaline and cocci were the predominating organisms in the succeeding attacks. In five cases the urine was alkaline throughout the course of repeated attacks, a coccus infection being present in every instance. The calculi found in the cases presenting alkaline urine and cocci were largely phosphatic in composition.

It is evident that a colon bacillus pyelonephritis may subsequently become infected, in some cases at least, with staphylococci attended with the not infrequent complications of such chronic infections—calculus formation.

The mechanism of stone formation in infectious lithiasis has not been worked out. The significant fact is the recognition of the important rôle now attributed to infection with the coccus group of organisms in the formation of urinary calculi. Their action appears to be twofold: (1) the urea-splitting action which determines the chemical composition of the stone and (2) they form the organic framework of the nucleus and the body in the staphylococcus stones.

This appears on first reading a rather startling conclusion and yet a careful analysis of reliable data furnished by a careful follow-up over a period of years of infected cases reported upon discloses a good deal of solid evidence in its support. Coccus infection of the calculous kidney is a much more serious complication than has been generally supposed. In the light of our present knowledge and experience there is need of a complete and more careful correlation of all available clinical data obtained by an intensive study of this important group of cases. Particularly important is the study of late results and a revaluation of our methods of treatment in the light of the results which such a study reveals.

CLINICAL APPLICATION

During the past few years the important rôle of infection by urea-splitting organisms, of which cocci are the most important in recurrence of stone, has been recognized. And attempts to improve the results of surgery of calculous disease have been made by various methods of attack upon the infection when present and its prevention following conservative operations. We have come to appreciate the importance of free ureteral drainage in combating all types of infection of the upper urinary tract, acute as well as chronic. The kidney is an efficient self-irrigating organ, and under normal conditions the pelvis and calyces are constantly and thoroughly flushed out. Proper function of this admirable mechanism requires free, unobstructed drainage of the ureter. Obstruction of any degree and from any cause to free drainage at or below the pelvic outlet interferes with this function. This fact is confirmed by daily clinical observation. In combating infection, therefore, it is of paramount importance to maintain adequate

drainage. For this purpose the ureter catheter fulfils one of its most important uses. Intermittent ureteral catheterization or the indwelling ureter catheter permits the direct application of various antiseptic solutions to the renal pelvis. I am not greatly impressed with the value of these from my own experience, but am inclined to believe the free drainage secured by the catheter is much more important.

Recently Randall has suggested the topical application of one per cent phosphoric acid to the renal pelvis for prevention of earthy (triple) phosphatic calculi. This suggestion is based upon the observation that 'bacteria often have a very limited range of chemical reaction in which they thrive; change their cultural habitat and bacteriostatic or bactericidal action is obtained'. The specific character of these recurrent stones is thus recognized; the treatment suggested aims at their removal or prevention by changing the reaction of the urine and in this way eliminating the specific infection. Various solutions, chiefly acids, have been used by other observers both by mouth and for topical application in an effort to dissolve pelvic and ureteral stones. Keyser states he has recently been interested in the organic acids, malic, citric and tartaric. Experiments with malic acid have yielded some interesting results.

In lightly-infected cases otherwise favourable for a conservative operation, pelviolithotomy, for example, an internal antiseptic supposed to be effective against the coccus group, such as pyridium, seranium or acriflavine should be used as a routine. Intravenous neosarsphenamine given the day before operation may be helpful in reducing infection. We have recently employed this combination with apparently good results. These patients must be followed with unusual care after operation and every effort made to completely eliminate infection. In a recent case of infected ureteral stone a rather severe infection associated with dilatation of the pelvis cleared up completely after operation under pyridium alone. Another case secondarily infected following leakage for ten days cleared up completely and promptly under the same simple treatment. With a better understanding of the problem presented by this group of cases and a keener appreciation of our responsibility it is my belief that our present methods of treatment suffice to cope successfully with the situation in the majority of cases without resorting to more radical surgery which appeared necessary only a few years ago. However, in the occasional case where the disease is limited to one kidney which has become seriously compromised by deep-seated and destructive inflammation nephrectomy is the operation of choice and is, in fact, a conservative operation in so far as preservation of the opposite healthy kidney is concerned.

Carbarsone

(Abstracted from the *Journal of the American Medical Association*, Vol. CIII, 28th July, 1934, p. 258)

CARBARSONE is a product of Eli Lilly and Company, originally proposed by Leake and his collaborators as a therapeutic agent in intestinal amoebiasis. In view of subsequent publications on the use of this therapeutic agent and a report from the A. M. A. Chemical Laboratory that the product is satisfactory chemically, the Council has now accepted Carbarsone-Lilly for inclusion in N. N. R. and has authorized publication of the following report:

Carbarsone is designated chemically as *p*-carbamido-phenylarsonic acid. It is closely related to tryparsamide; in common with both acetarsone and tryparsamide, it is a pentavalent arsenic compound.

An investigation carried out at San Quentin prison by Reed and his associates on the incidence of amoebiasis in newly-admitted prisoners and in the food-handling force of the institution, and the treatment of these cases with vioform or carbarsone, has been the subject of a series of progress reports. The final

report covers ninety-two treated cases, of which twenty-nine were removed elsewhere before any significant follow-up period could be established. Of the remaining sixty-three, thirty-one had been treated with vioform and thirty-two with carbarsone. Stool

examinations (smears stained with iron hæmatoxylin) were made on three consecutive days at intervals of from two to four weeks on each patient. The vioform group was followed for an average period of 13.2 months (range, 7 to 18½ months); all but three of these patients remained negative (the latter were found to be positive at eight, ten and sixteen months, respectively). Of the carbarsone group, all thirty-two remained negative for an average period of 19.6 months (range, 13½ to 22 months). Of the original series of forty-two cases treated with carbarsone, one severe case did not remain negative after two courses. Of four others in which 5 gm. of carbarsone was given in ten days, two showed recurrences six and seven weeks, respectively, after treatment. After a second course of carbarsone, these two remained negative for the one month of observation. All four patients were paroled before the follow-up period could be completed.

It appears from this unusually well controlled study, in which the possibility of reinfection was apparently relatively low, that carbarsone may be an unusually effective treatment in amœbiasis.

Presson presents results in forty cases of protozoiasis treated with carbarsone (eighteen *Entamœba histolytica* alone, five *Entamœba histolytica*, associated with other protozoa; the remainder were *Entamœba coh*, *Entamœba nana*, *Trichomonas*, *Giardia*, *Chilomastix*, singly or mixed). One course of 0.25 gm. of carbarsone twice a day for ten days cleared all but two cases (one *Giardia*, the other *Entamœba histolytica*, *Chilomastix* and *Trichomonas* mixed); from six to fifty follow-up examinations were made in each case but the periods of observation are not stated. The only side effects reported by Presson were flatulence and 'hyperperistalsis' of the intestine but 'no excessive diarrhoea'.

Anderson and Reed state that about 10 per cent of patients with amœbiasis are found to be refractory to carbarsone orally. These are cases usually of acute dysentery or diarrhoea in which motile amœbas are found. The authors present twelve cases in which carbarsone was administered rectally (200 c.c. of a solution containing 1 per cent of carbarsone and 2 per cent of sodium bicarbonate) as an overnight retention enema, on alternate days for five such treatments. Usually a sedative was administered to permit retention of the enema; three patients could not retain the dose. Oral treatment was interrupted to avoid overdosage. The enemas relieved the acute symptoms but the amœbas were not eradicated. Eight of these patients received carbarsone by mouth subsequently; four had one course, two two courses, and two three courses. In addition, adjuvants such as bismuth subcarbonate, vioform, acriflavine, heptylresorcinol and emetine were used variously in seven patients. The latter, and five patients receiving carbarsone alone, remained amœba-free for an average period of five and one-fourth months; but two of the first group

were found positive again at six and twelve months, respectively. These authors believe that patients should be followed for a period of two years after completion of therapy. Of course, in a period as long as this, as has been pointed out, it is impossible to distinguish recurrence from reinfection.

Anderson reports eighty-eight cases of amœbiasis in Panama treated with carbarsone. Eighty adults received a total of 5 gm. in ten days; six children received about one-half the adult dose; two patients did not complete treatment. Thirty-seven of these cases were followed for a month (six or more specimens) and all but one were cleared and remained so for the period of observation. The data on the others are incomplete.

Chopra, Sen and Sen (*Indian Med. Gaz.*, Vol. LXVIII, p. 315) investigated the effectiveness of carbarsone in thirty-one cases of amœbiasis treated in Calcutta. Twenty-three had five or more (most had six) negative examinations on different days following cessation of treatment; four patients appeared to be cleared but the authors consider the number of post-treatment examinations insufficient. There were four failures. It is obvious that, as the authors admit, the criterion of cure used by them is not adequate for reasonable certainty of an ultimately satisfactory result. Nevertheless, the results obtained, as judged by this method, appear to be better than those obtained in India with the other agents commonly used. Chopra and his associates agree with the oft-repeated claim of the California workers that carbarsone is superior in therapeutic efficacy to acetarsone.

Anderson and Reed report one case of toxicity from carbarsone. This consisted of icterus, pain in the right upper quadrant, enlarged tender liver, numbness of the hands and legs, weakness and 'generalized aches' in a patient who one year previously had had an enlarged tender liver following carbarsone therapy. The symptoms cleared in five days with no apparent residual effects. In addition, seven cases of gastric irritation occurred with a preparation purified by a different method, since abandoned.

Anderson and Reed state that they have seen no evidence of skin, optic nerve or renal damage following the use of carbarsone clinically. The possibility of optic nerve destruction has been particularly emphasized, as carbarsone contains a modified amino group in para position to the arsenic atom, similar to the arrangement in tryparsamide. Farrington (reported by Anderson and Reed) administered graded doses up to totals of 150, 300, 600, 800 and 1,200 mg. per kilogram over a period of forty-eight weeks (alternating four weeks of administration with four weeks of rest) without evidence of toxicity in thirty-three cases as determined by clinical examinations (including visual field determinations) and tests on blood and urine, all at intervals of four weeks.

In one case reported to the Council, 0.25 gm. was given twice a day for six days. On the fourth day severe headache developed, which persisted in milder form for the two subsequent days, on the fifth generalized itching occurred and on the sixth a light scaling erythematous rash was noted on the forearms. Administration was stopped and symptoms of toxicity cleared up largely within forty-eight hours.

Dr. Frank Smithies, in a discussion before the Chicago Society of Internal Medicine, 28th May, 1934, and in a subsequent written communication, reported several cases of severe toxic reactions from the administration of carbarsone in 0.25 gm. capsules:

'1. One patient with acute amœbiasis took less than ten capsules of carbarsone and within a week had a dermatitis of the exfoliative type over the hands and arms.

'2. One patient took twenty capsules of carbarsone (three capsules daily) and experienced, after the fifth

day, pulmonary edema, edema of the larynx, chemical sore throat and very pronounced sneezing, lacrimation and running of the nose.

'3. One patient took carbarsone five days on and one week off (two capsules a day) and six weeks after treatment was begun came to me with a history of acutely swollen ankles, knees and wrists—a condition which the patient had never experienced before and which came on about the fourth week following the beginning of carbarsone therapy. When I saw him he had, in addition to moderate swelling about the soft parts of the joints named, a liver four finger-breadths below the rib margin (it was tender) and a spleen at least twice the normal size (it was readily palpable).

'4. One patient, who took seven capsules of carbarsone over a period of three and one-half days, developed faulty vision and photophobia. There was moderate swelling of the eyelids, slight puffiness of the face and granular casts with a trace of albumin in the urine. Ophthalmoscopic examination showed moderate papillitis and moderate retinal edema.

'5. Several patients experienced aggravation of diarrhoea, nausea and vomiting and vague pains, in the stomach region, after from two to eight carbarsone capsules had been taken. One of these patients developed slight but definite icterus on the fourth day after beginning carbarsone therapy (two capsules a day)'.
'

Dr. Smithies deprecates the present tendency toward the indiscriminate administration of fixed total doses of anti-amoebic drugs without regard to the sensitivity of the individual patient (or to the tissue damage that such remedies may produce) and often even without adequate diagnosis. He points out that adequate therapy often requires the use of a number of remedial agents and cautions against placing too much reliance on single 'specific' remedies.

Reed emphasizes the necessity of determining by suitable tests the presence or absence of hepatitis (and impairment of renal function), guarding the use of arsenicals accordingly. He warns against over-standardization of treatment and points out the frequent necessity for adjuvant therapy, such as alternating courses of vioform with those of carbarsone, with ten-day rest periods intervening; tannin preparations and bismuth subcarbonate in cases presenting persistent dysentery or diarrhoea; emetine in amoebic hepatitis; dietary adjustment; colonic irrigations with antiseptics and other measures for secondary infection; proper surgical intervention when indicated in resistant cases.

Reed and Johnstone summarize the results in 330 cases: 'Our conclusion is that carbarsone is a valuable addition to the treatment of amoebiasis because of an effectiveness at least as high as any other single drug, combined with low toxicity, capability of oral administration, non-interference with ordinary pursuits of the patient, lack of adjuvant requirements such as bed rest, diet, hospitalization and other drugs, and finally its relatively low cost. We have found a certain number of patients resistant to carbarsone and all other therapy'.

It appears that carbarsone is a valuable addition to the anti-amoebic armamentarium. It must be considered, however, that not a few patients are resistant to this agent as well as to other amoebicidal drugs, and that, while toxic reactions appear to be uncommon, a few serious accidents have occurred after administration of the usual therapeutic doses of carbarsone. The individual susceptibility to arsenic compounds of each patient must be evaluated and evidences of toxic manifestations must be watched for carefully, both during the period of therapy and, in view of the slow excretion of the administered arsenic, for a reasonable time afterward.

Immunization against Yellow Fever

(From the *Lancet*, 3rd November, 1934, Vol. II, p. 994)

THE discovery by Max Theiler in 1930 that mice are susceptible to yellow fever on intracerebral inoculation opened a new chapter in the history of immunization against this disease, since the use of mouse-fixed or neurotropic virus for protecting human beings seemed to overcome many of the difficulties attendant on the use of the ordinary or viscerotropic strain of yellow fever virus. Two methods of vaccination have been employed. In the first, initiated in New York by Sayer, Kitchen and Lloyd, a combination of titrated human immune serum and neurotropic virus was injected. This method has been used by Findlay in London and by Pettit and Stefanopoulou in Paris, where, however, instead of human immune serum one prepared from the horse has been employed. Rather more than 400 persons have now been immunized by this method and the immunity has been found to last for well over two years.

In 1932 Sellards and Laigret began vaccinating volunteers with small doses of neurotropic virus alone, but the reactions were in some cases very severe. Laigret therefore proposed to attenuate the virus by exposing the infected mouse brains to a temperature of 20°C. for four days, two days, and one day—a process analogous, according to Laigret, to that used in attenuating rabies virus. The brains were then either preserved in glycerine or desiccated, frozen and kept in the ice-chest. After titration in mice they were inoculated into volunteers. Three inoculations were given at intervals of 20 days; the first consisted of 1 c.cm. of a 1 in 100 dilution of four-days' mouse brain, the second of 1 c.cm. of a similar dilution of two-days' mouse brain, and the third of 1 c.cm. of a similar dilution of one-day's mouse brain. Recently Laigret has reported the results of immunizing by this method more than 3,000 people, mostly whites, in French West Africa. The results would perhaps have been of greater value if by previous tests an attempt had been made to ascertain whether any of these persons were previously immune. Although immunity was satisfactorily produced, about a third of those immunized developed febrile reaction on or about the sixth day, commonly after the first, more rarely after the second or third injection; in two cases there were symptoms of cerebral involvement. These results are perhaps not unexpected, since the injection of living, even though attenuated, neurotropic yellow fever virus in the absence of immune serum has very considerable danger.

Dr. G. M. Findlay records experiments on monkeys injected with infected mouse brains attenuated and titrated by Laigret's technique which show that brains attenuated for four days at 20°C. either give rise to circulating virus, or, if virus cannot be detected in the blood stream, they fail to immunize: brains attenuated for one or two days always give rise to the presence of living virus in the blood. After one of the three injections, therefore, virus is almost certain to circulate in the blood stream although, owing to the wide variations in individual susceptibility, it need not necessarily give rise to clinical symptoms. Any person with neurotropic yellow fever virus circulating in the blood stream, however, is a potential danger both to himself and to the community in which he lives. Personal danger lies first in the fact that the barrier between the blood stream and the brain may sometimes break down so that cerebral lesions result. In animals, as mentioned by Dr. Findlay, there have been instances in which, after subcutaneous or intraperitoneal inoculation of neurotropic virus, encephalitis has developed in the absence of any cerebral trauma, and Laigret himself records involvement of the nervous system in man. A second personal danger lies in the fact that in some people the neurotropic virus may give rise to jaundice and albuminuria as well as to

leucopenia and bradycardia. Evidence is also accumulating to show that in animals the neurotropic virus is capable of producing visceral lesions and is pantropic rather than strictly neurotropic. It is, therefore, not impossible that neurotropic virus inoculated subcutaneously into man may on occasion revert to the viscerotropic strain. Finally, any person with neurotropic virus circulating in the peripheral blood stream is a potential danger to the community if he lives in a country such as West Africa, where *Aedes aegypti*, the mosquito vector of yellow fever, is also present. Although Mathis, Laigret and Durieux (1934) state that no epidemic followed their mass immunization, experiments by Davis, Lloyd and Frobisher (1932) and by Roubaud and Stefanopoulo (1933) have shown that mosquitoes can take up the neurotropic virus from the blood stream of monkeys and transmit it to other monkeys, while Davis has recently demonstrated that at every bite the infected mosquito injects at least 100 times the minimal infective dose for a mouse. Every person, therefore, vaccinated with living neurotropic virus alone should, if resident in a mosquito-infected country, be kept screened from mosquitoes from the time of inoculation of virus until the development of immune bodies in the blood—a period, if Laigret's method be employed, which might last for some weeks.

Hence it seems very doubtful if, with our present knowledge of the potentialities of the neurotropic yellow fever virus, mass immunization with living neurotropic virus alone can in any way be justified, more especially when carried out in a country such as West Africa where *A. aegypti* is present. On the other hand, immunization with living neurotropic virus and immune yellow fever serum provides, as shown by many observers, a reasonable method of reducing the possibilities of virus circulating in the blood stream. It will be the safest and most satisfactory means of immunization until such time as it becomes possible to produce a virus, which is antigenically potent, but devoid of pathogenicity.

Ear-Ache and its Treatment

By JOHN F. O'MALLEY

(From the *Practitioner*, Vol. CXXXIII, September 1934, p. 234)

PAIN is nature's herald of distress, a signal, a call for help. Its severity is not always a true measure of the gravity of the complaint which calls it forth, as it may be conditioned by such factors as the type of infection, the anatomical structure of the tissues attacked, or even the tolerance of the patient. This is well exemplified in the case of middle-ear tuberculosis which, though a grave disease, is as a rule painless. Pain is excessively severe in inflammation which tends to end in suppuration, and cutaneous streptococcal inflammations, such as erysipelas of the ear and scalp, are extraordinarily sensitive to touch. Tissues which yield easily to inflammatory engorgement are less prone to intense pain than those in which oedema is very circumscribed by virtue of their structure, and so for the latter reason all the adnexa of the hearing apparatus are peculiarly subject to severe pain when inflamed. This applies particularly to perichondritis of the pinna and meatal tube, as well as to inflammation of the Eustachian tube and tympanic membrane. Yet, again, there may be a great predominance of pain in one ear, although the clinical signs may indicate the same involvement in both, hence the wisdom of a bilateral examination in all cases.

Pain in the ear may be associated with two general groups of affections: the first being direct or localized and due to inflammatory disease in any part of the auditory apparatus; and the second indirect or referred, arising from disease in adjoining portions of the scalp, jaws, nose, or throat. For instance, in the

former a definite lesion will be discoverable in some portion of the hearing mechanism by anyone who has the necessary skill, and, if none can be found to explain the ear-ache, the cause must be sought in regions from which pain may be referred to the ear. In this connection it is worthy of note that a lesion anywhere in the area of distribution of the trigeminal or glossopharyngeal nerves or in that of the superior laryngeal branch of the vagus, may cause referred ear-ache. A classification of the two groups may therefore be usefully set forth as below:—

(1) Direct or localized pain.

- (A) External ear. (a) Pinna (b) Meatus

- (1) Herpes
(2) Eczema
(3) Erysipelas
(4) Perichondritis
(5) Furunculosis
(6) Impacted wax
(7) Exostosis

(B) Eustachian tube

- (C) Middle ear (a) Acute inflammation and suppuration.
(b) Chronic inflammation and suppuration.
(c) Non-suppurative disease (catarrh, otosclerosis).

(D) Mastoid.

(2) Indirect or referred pain.

(A) Teeth and alveolus.

- (B) Nasal accessory sinuses { (a) Maxillary } Suppuration,
(b) Sphenoidal } malignant
(c) Ethmoidal } disease

(C) Nasopharynx.

Pharynx Tuberculosis, carcinoma.

Larynx

Œsophagus—post-cricoid carcinoma.

(D) Fauces

{ Tonsillitis (acute, chronic,
calculus).
Quinsy.

(E) Tongue—ulceration.

(F) Temporo-mandibular arthritis.

(G) Neuritis of great auricular nerve.

Pinna and external meatus.

Herpes affecting the external ear alone is a rare condition, but is more common in association with that of the face or neck. Pain of a shooting or stinging character may precede the outbreak of vesicles by some days and is usually accompanied by some pyrexia and general febrile symptoms. It may accompany an attack of pneumonia. Cold compresses relieve the pain, but these should be replaced by a dry starch powder and cotton-wool dressing on the appearance of the vesicles.

Eczema, when acute and in the weeping or vesicular stage, causes a burning sensation, which is relieved by the free application of calamine lotion.

Erysipelas.—This condition is passed over rather lightly in the textbooks on diseases of the ear, but in my opinion it deserves serious attention on account of the diagnostic traps in which it may involve the unwary. It is generally a part of a cutaneous infection of the scalp in the mastoid region or of the face in front of the ear. The portal of infection is frequently a small eczematous fissure in the external meatus and the cutaneous involvement may be first noticed over the mastoid with a burning pain in the ear. As it is accompanied by high fever, an investigation of the site of pain (if localized around the back of the pinna) may lead to the diagnosis of mastoiditis, as this region is usually red, slightly oedematous, and exceedingly tender to touch. I have come across about 20 cases in as many years and was actually called upon to operate on 4 of these as acute mastoiditis, but was fortunately able to avoid doing so owing to the lesson provided by the first case.

It was one of chronic middle-ear suppuration under my care in a military hospital during the war and

seen by me two days before I was summoned urgently, late one evening, to operate for acute mastoiditis. The scalp had been extensively shaved in preparation for operation, revealing redness and edema of the scalp far beyond the mastoid region. It was all very tender to touch, even in areas remote from the mastoid and this revealed its true nature.

All my later cases have provided similar areas of tenderness far beyond those found in mastoiditis.

The pulse and temperature ratio is also peculiar, in that it resembles that of enteric fever, which is quite unlike the ratio seen in acute mastoiditis or any of its complications. The pain is relieved by the application of cold water, which was first advocated by Hippocrates. It is still as effective as any of the newer local remedies; but covering the part with starch powder and wool is more convenient; this, and the injection of a specific serum, constitute the modern method of treatment.

Perichondritis of the pinna is relatively rare; it may arise from a scratch or the spread of infection from a boil in which event the whole outer ear, with the exception of the lobule, may be involved. In many cases of furunculosis in the outer end of the external meatus, a small area of perichondritis will be seen, posteriorly, in the concha, but it remains limited to this area, although it adds considerably to the pain. Involvement of the whole pinna assumes all the characteristics of a cellulitis, and there is the danger that the cartilage may be destroyed with resulting deformity. Heat is the best early treatment for the relief of pain, but, if edema is present, several short incisions to relieve tension, under general anaesthesia, are indicated to prevent cartilage destruction. Some surgeons advise puncture right through the pinna in several places with a small scalpel, after first painting the whole surface with iodine or picric solution.

Furunculosis.—This is a very common affection of the external meatal tube, the boil having its origin in a hair follicle or ceruminous gland and it may be preceded by a slight eczema. In its developing or pre-suppurative stage it is usually exceedingly painful owing to the restriction of inflammatory edema caused by the closely adherent skin of the meatus but on the escape of pus the pain subsides. Although deafness due to blocking of the meatal passage may be present and noticed by the patient for a day or two, pain is the outstanding symptom for which relief is sought. Cold or heat will modify the aching. Some surgeons prefer the former and apply Leiter's ice coil. Personally, I prefer heat and employ some means which insures the maintenance of the highest bearable temperature for as long a time as possible. Fomentations cool off rapidly and need too frequent renewal, so to fulfil this need I use antiphlogistine or similar preparations and find them quite satisfactory. Five per cent glycerine acid carbolic used as drops has a soothing and abortifacient effect, being at the same time antiseptic and analgesic. It, however, tends to cause peeling of the meatal epithelium, which may possibly lead to re-infection later and recurrence. If used, and it is decided to apply heat subsequently, all traces of the carbolic should be first removed or blistering may ensue. If edema and pain are intense, an incision, under general anaesthesia, may be necessary. The point of the scalpel should be inserted deep in the meatus beyond the swelling and then the cut made outwards. It must be incised down through the base of the boil or relief of pain will not result, but on the contrary it may be intensified. Boracic fomentations should follow for twenty-four hours.

Impacted wax.—A plug of wax long retained in the meatus may start a dermatitis and an exudate which causes the wax to swell, the pressure of which on the inflamed surface results in ear-ache and possibly some tenderness or pain behind the ear or side of the head. The patient complains also of increased deafness and autophony (if the hearing was previously good) with, in some cases, discomfort and pain on mastication.

If the outer end of the meatus is small and the wax plug has a hard central core, attempts at its removal by syringing are unwise before using some means of softening it for a few nights previously. In such a case the syringe jet must impinge directly on the plug and force it against the drum, which may damage the latter. Thirty grains of bicarbonate of sodium and 2 drachms of glycerine to 1 ounce of water make a good wax softener if the meatus is filled nightly with it; but if ear-ache is a feature of the case I prefer to use olive oil, carbolized to 2 or 3 per cent. This oil, used warm and dropped into the ear every four hours for one or two days, will soothe the aching and soften the wax sufficiently to permit its removal subsequently by syringing with bicarbonate of sodium solution, 2 drachms to the pint of warm water.

Exostosis.—This is a single bony outgrowth which narrows the lumen of the canal and is generally situated about half an inch inwards from the outer end. At a first glance it may be mistaken for a boil, if such is suspected, but it is solid to touch with a probe. Usually it does not cause any pain, unless it is so large as to press on the opposing meatal wall, when a dermatitis may result. If large enough to occlude the meatus, advice should be sought on the question of its removal which should not be lightly undertaken by those unfamiliar with the technique and risks attendant upon what may be considered an apparently simple surgical procedure. An exostosis may cause impaction of wax together with meatal pressure and pain, and this should be treated in the manner advised above for impacted wax.

EUSTACHIAN TUBE

An inflammatory involvement of this usually precedes that of the middle ear and the pain is localized in the region behind the angle of the jaw, in front of the anterior border of the sterno-mastoid muscle and below the lobule of the ear. It is often preceded by pain lower down in the region of the tonsil, which is felt below the angle of the lower jaw, in the anterior triangle of the neck; so that there may be a sequence of pain, first below the angle of the lower jaw, next above and behind it, and then in the depth of the meatus and even still later in the mastoid. This is the common order of involvement of the middle-ear spaces arising from an infection of the fauces and the tonsillar region, and in many cases this sequence will be recalled by the patient when the memory is put to the test. It may be regarded as spread of infection by continuity from the fauces and nasopharynx, not specifically related to epidemic colds. On the other hand, in the respiratory infections of the upper air-passages associated with the exanthemata and influenza, the symptom of pain may be first experienced in the tympanum, due to the greater incidence or effect of the inflammatory reaction here. In the efforts to keep the nasal passages clear and comfortable, the frequent or forcible use of the handkerchief may carry the infected products of inflammation into the middle-ear cavity, and the resulting reaction and engorgement soon reach the limits of their possible distribution before tension and pain become manifest.

Eustachian tube pain may be treated by the frequent inhalation of steam impregnated with tinct. benzoin. co or menthol, in addition to the methods mentioned below under the heading 'middle-ear inflammation'.

MIDDLE EAR

Acute middle-ear inflammation.—Pain is an outstanding symptom of this condition, due, in the early stages, to engorgement of the tympanic cavity lining and accompanied by an increasing deafness and moderate pyrexia. As the case progresses towards suppuration, physiological inflammatory exudates accumulate in the cavity and, as there is now no possible escape through a swollen Eustachian tube, distension takes place at the expense of the only mobile wall, the tympanic membrane, and so the pain

becomes intensified and is often exasperating. It is usually boring and throbbing in character, the throbs corresponding in rate to that of the pulse beat. A thin membrane may give way and relieve the tension quite early in the exudative stage, but a tough one may not do so for some days.

In the early stage of ear-ache, with slight deafness, pyrexia, and only redness of the membrane, expectant treatment should be carried out, as many such cases occur, which never proceed beyond this phase, but which if surgically incised must suppurate, no matter how aseptically the operation is performed. The patient should stay indoors and drop 2 per cent glycerine acid carbolic solution into the ear three times a day, kept in by a small piece of cotton-wool, over which a large pad is placed, and then lie on a hot water bottle. This relieves pain. A dose of calomel (three grains) and ten grains of aspirin on going to bed, followed next morning by a saline, may terminate the attack.

If the pain, deafness, and pyrexia increase, the case is passing into the exudative inflammatory stage and will end in suppuration. An examination of the membrane will now reveal oedema and bulging. To interpret these changes correctly under either direct or reflected light requires a considerable degree of practice and experience, owing to optical illusions of planes of surfaces and colour changes, but if they are present the immediate release of tension is indicated.

Spontaneous perforation or a simple paracentesis will answer the primary physiological needs for the relief of pain, but they are not satisfactory in permitting the free escape from the cavity of any thick inflammatory products, to enable its rapid restoration to its air-space function. To insure this, a curved incision with its concavity upwards and forwards somewhat like a very open letter U is best and should be made in the entire extent of the posterior half of the membrane. A sterile ribbon gauze dressing, lightly filling the meatus, should be inserted and left *in situ* for two days.

Chronic middle-ear suppuration.—Pain is relatively rare in chronic suppurative lesions of the middle-ear air spaces, this being especially so if the perforation or absence of drum is sufficiently large to afford free escape of discharge and release of inflammatory tension. When present it may only amount to an occasional twinge, the chief discomfort arising from deafness and discharge. Even the latter in many cases is not sufficient in quantity to escape at the external meatus, because it evaporates in the passage to accumulate as debris mixed with wax. This absence of pain is probably the reason why the patient tends to ignore the gravity of the disease and so consequently omits or neglects to have the condition persistently and properly treated. This also explains why our medical forefathers regarded the escape of discharge as harmless, so long as it was not accompanied by pain, but arrest of the discharge with the onset of pain they had learned by experience to look upon as grave symptoms, often followed by fatal consequences.

It is now known that this development was due to an intracranial extension of the disease from the primary erosion in the middle ear, which was the previous source of the discharge. The latter has now invaded the cranial cavity, setting up, usually, in the first instance an extra-dural abscess, lying between the dura mater and the bony wall of the cranium. Inflammation of the dura mater (pachymeningitis) is invariably present in such cases, so that pain becomes a very prominent symptom, in the form of a severe continuous headache, on the affected side. The site of the lesion most likely to be followed by such a sequence of events is either in the roof (attic) of the middle ear, the aditus leading to the mastoid antrum or, in the latter, with a perforation high up in the tympanic cavity.

The type of the suppurative lesion most prone to cause intracranial extension is that known as cholesteatoma, so called because cholesterol crystals are found between massed layers of epithelial cells. The continued increase of these layers is at the expense of the underlying bone, so that an invasion of the cranial cavity may ensue, by erosion of the intervening bony wall. About 33 per cent of all cases of chronic middle-ear suppuration are accompanied by this condition, which should always be suspected if the discharge has a very foetid odour.

Recurring acute exacerbation.—Attacks of acute inflammation may recur in cases of chronic suppuration, causing an exacerbation of the latter with increased aural discharge and some ear-ache. The pain is rarely severe and never as bad as in a primary acute middle-ear inflammation, because, as already pointed out, the presence of a perforation releases the tension of inflammatory swelling and discharge. The pain is usually felt in the tympanum, but may spread to the mastoid, the latter being tender to pressure, which will raise the serious problem of an acute mastoiditis. This complication arises occasionally from these exacerbations. For the tympanic pain, the use of 3 per cent glycerine acid carbolic is indicated and usually suffices to give relief.

Erosion of the attic roof and outer wall.—In my experience ulceration of bone in this situation is usually accompanied by neuralgic pains above the ear, radiating to the vertex, which cause the patient a considerable degree of discomfort at times. The pain is possibly aggravated by a periostitic patch of the inner end of the meatal roof, infected by extension from the attic erosion. The presence of the lesion is revealed by some granulation and thick pus, usually devoid of mucus, at the junction of the meatal roof and Shrapnell's membrane. The periostitis is actually outside the middle-ear air spaces, which may explain the radiating pain.

Sometimes an examination of the tympanic membrane may reveal the pulsation of pus in the perforation. If this is seen in the attic region, in a chronic case, and is accompanied by arrest of discharge from the ear, together with the sudden onset of severe unilateral headache, it raises a strong suspicion of an extra-dural abscess, the pulsation being conveyed from the dura mater to the pus in the perforation. Pulsation of pus in the perforation is also a very common occurrence in acute middle-ear suppuration, due to the inflammatory engorgement of the mucous membrane, which is also the cause of the throbbing pain. This is not to be confounded with the above. In the acute condition the pulsation appears during the calm after the storm of symptoms and is a benign indication of the usual physiological progress, but in the chronic case it appears only during the storm and is of malignant import.

A useful working rule is that an aural discharge usually diminishes or ceases with the onset of intracranial complications arising from either acute or chronic middle-ear suppuration. If the arrest be accompanied by pain and moderate pyrexia in chronic cases, a pachymeningitis and extra-dural abscess should be suspected, and if in acute cases with a high pyrexia, say 104°F. or more, a lateral sinus thrombosis is the more likely cause. High pyrexias have a tendency to diminish all secretions and discharges, even those of inflammatory origin. Either may occur without any localizing sign in the mastoid region and, as the treatment is promptly surgical, the most skilled help obtainable should be summoned immediately.

Non-suppurative diseases of the middle ear.—To this group belong middle-ear catarrh and otosclerosis, in which gradually increasing deafness is the dominant symptom and ear-ache a minor one. In both, however, there may be fleeting darts of pain at times, but these are rarely more than momentary twinges and seldom call for any special treatment. A record of its occurrence is important, as suggesting the presence of a low

grade inflammatory process, the recognition of which renders the prognosis to hearing more grave, this being especially so when arising in patients with a family history of deafness.

PERFORATIONS AND SCARRING OF MEMBRANE

Nasal obstruction, perforations and scarring of tympanic membrane.—Patients with nasal obstruction frequently have contact areas of opposing mucous membrane in the nose, which cause discomfort and excessive secretion, for the relief of which the habit of sniffing is resorted to. The frequent repetition of this respiratory act may cause excessive and sudden withdrawal of air from the tympanic cavity and produce a partial vacuum. This may cause an ear-ache of short duration in two ways: First, by a responsive engorgement of the mucous membrane lining, to meet the sudden diminished pressure of the partial vacuum created in the cavity; and secondly, for the same reason, from sudden stretching of the tympanic membrane wall of the cavity by external atmospheric pressure in the meatus. Persons with a moist catarrhal mucous membrane acquire this sniffing habit, and I have no doubt that it is a potent mechanical factor in starting air-pressure disturbances in the middle-ear space which gradually lead to deafness. Attention to the nasal condition is necessary in these cases. A warm alkaline nose wash and inhalation of menthol vapour give some relief. I have come across some cases of large open perforations of the tympanum or attic, with a dry and completely healed lining, in which slight pain was complained of, especially in cold weather or if exposed to the draught of an open window or that of a motor car. I have also heard of a process of the incus was caught up in a scarred membrane. This exposure may also cause giddiness in some of these very sensitive patients. Keeping the ear warm and protected by a piece of wool when exposed is sufficient treatment.

Mastoiditis.—This is secondary to an inflammatory infection of the middle-ear cleft, which anatomically implies the Eustachian tube, middle-ear cavity (atrium and attic), the aditus, and mastoid antrum. In extension of these we must include the mastoid air cells of the typically developed mastoid or the cancellous centre of the atypical bone. In rare cases suppuration may be manifested first in the mastoid, without any active inflammatory sign being present at the moment in the middle ear, although the primary infection of the former had travelled across the latter, but cleared up. With the primary infection of the middle-ear cleft air spaces, pain may be felt in the mastoid synchronously with that of tympanic ear-ache, but with the onset of middle-ear suppuration the mastoid pain often subsides, to develop later, if suppurative activity in the antrum or air cells should ensue.

Tenderness to pressure over the bony process may be present with the first and second manifestations of pain, but disappears during its absence. If the tenderness to pressure accompanying the early tympanic and mastoid pain is felt as low as the tip of the process, it is some evidence of a wide infection and of the bone being of the cellular type. For the same reason the development of mastoiditis is more probable than if the tenderness be restricted to a small area just over the mastoid antrum. If the tenderness to pressure accompanying the second onset of mastoid pain which follows middle-ear suppuration be felt only over the antrum region, one should suspect an atypical or non-cellular type of bone with a forward lateral sinus, because in the cellular variety of mastoid the tenderness is greatest at the tip or above this on the posterior border, where the inflamed air cells come closest to the periosteal surface. This is a point of considerable surgical importance, as the difficulty of operative technique is greatly increased by the presence of a forward lateral sinus; for to avoid wounding it in the approach to the antrum much care and skill are

required, whereas to open the antrum in the typical cellular mastoid this risk is comparatively small.

The primary pain in the region of the mastoid antrum associated with middle-ear suppuration is most likely the result of inflammatory engorgement in the aditus, just as a similar involvement of the fronto-nasal duct will cause frontal pain, with a maxillary sinus suppuration, though the frontal sinus is radiologically free from any evidence of change. This primary pain and tenderness usually subside as the middle-ear suppuration progresses and if the latter is favourable may not return, so treatment is therefore directed to the general systemic and middle-ear condition.

To relieve mastoid pain heat or cold is about equally effective though the continuous maintenance of the application is the point of greatest importance and for this purpose antiphlogistine or similar preparations are very comforting. Avoid excessive heat as it may give rise to fictitious signs of mastoiditis, such as redness and soreness. Mastoid pain and tenderness, associated with an active middle-ear suppuration, which occur some days after the onset of the latter, whether preceded by a previously observed attack of pain or not, are more grave symptoms because they set in when the exudative stage of the inflammatory process is at its height, and indicate that resolution of the inflammation in the bone has not been accomplished but that, instead, suppuration is developing. This process may now spread to the cortex of the bone, causing a periostitis with oedema of the periosteum and its covering tissues. It is now very painful and exceedingly tender even to slight pressure, but an incision down to the bone may not yet reveal any pus and even the interior of the mastoid may only show the intense engorgement of an acute osteitis. If allowed to develop further, the swelling will increase, the skin becomes red and pits easily. An incision now will reveal subperiosteal pus, with possibly an erosion on the mastoid cortex, commonly over the antrum, with frank pus in the bony interior.

This is the typical form of mastoiditis, as it occurs in children above five years of age and is far less grave than the form seen without any post-auricular swelling. The proper treatment is the mastoid operation known as Schwartz's. Below the age of five, a swelling may occur on the mastoid accompanying acute middle-ear suppuration, by extension of this process through the notch of Rivinus and not through the mastoid cortex. For this a simple Wilde's incision will usually suffice. The late onset of pain and tenderness (especially to deep pressure) with no oedema or outward sign and a continuing pyrexia, presents a far more serious problem. These are the cases which may lead to the gravest complications, as the infective process lies deep in the bone. For instance, inflammation in the group of mastoid cells lying behind the facial or Fallopian canal may give rise to a facial paralysis. This is not common, but the same seat of inflammation may cause an engorgement of the posterior labyrinth wall and set up a peri-labyrinthitis with vertigo. It also lies in very close proximity to the lateral sinus and may involve this, so that here we are confronted with a possible labyrinthitis, which may end in meningitis or lateral sinus thrombosis followed by general septicæmia or pyæmia.

REFERRED EAR-ACHE

When careful examination of the ear by anyone with the necessary experience can exclude any form of active disease or deafness, the source of the ear-ache must be sought for elsewhere. Some of the causes described below are rare, others are fairly frequent.

Teeth.—Caries of the teeth, and those of the upper jaw in particular, may cause pain in the corresponding ear. An impacted wisdom tooth is a not uncommon offender. If no other explanation is available and assuming that a dental caries is suspected, a

radiological examination may be necessary to establish or negative this suspicion.

Alveolus.—Bony inflammation, associated with dental caries, may cause ear-ache. The treatment in each case consists in dealing with the diseased focus.

Nasal accessory sinusitis.—Acute or chronic inflammation and suppuration of the maxillary or sphenoidal sinuses may cause referred ear-ache. It is possible, however, that they most commonly do so by their escaping secretions infecting the area around the Eustachian tube, a condition not easily diagnosable in many cases, owing to the difficulty of getting a proper view of the nasopharynx.

Ethmoidal region.—Sepsis in these cells may cause changes around the Eustachian tube and ear-ache. Carcinoma in this region has been known to cause pain in the ear.

Nasopharynx, pharynx, larynx, œsophagus.—Ulceration in any of these regions, whether simple inflammatory, tuberculous or carcinomatous, may excite referred pain in the ear. A knowledge of this fact may lead to the earlier examination and discovery of a growth, with the consequent better prospect of successful treatment. Post-cricoid carcinoma, a condition arising in the upper end of the œsophagus and decidedly more common in females than in males, may be responsible for referred pain to the ear at an early stage in its growth. Ear-ache, in the absence of any inflammation of the ear or deafness, should, in females over 50, attract attention to any throat symptoms present and to examination for post-cricoid carcinoma.

Fauces, tongue, tonsil.—Ulceration, or even acute inflammation in these structures, may be the underlying cause of referred ear-ache; for example, acute

tonsillitis and quinsy very commonly, and a tonsillar calculus in a tonsil may also do so. The post-operative ear-ache of tonsillectomy made worse by swallowing is frequent, though there is not any aural disease. Permanent relief of pain in all these cases depends upon the cure of the underlying condition, but temporary relief may be obtained in the acute forms by placing some warm oil and wool in the external meatus and over this a large roll of wool extending below the angle of both jaws and held in position by a bandage tied over the vertex.

Temporo-mandibular arthritis.—Pain in this situation, owing to its close proximity to the external meatus, may be regarded as ear-ache. The first step is to see that there is not a mass of hard wax present; and then to press over the joint as the patient opens or closes the mouth, which will elicit pain and tenderness. An irregular chewing bite may cause this pain; thus extraction of some diseased teeth, if a denture is not substituted, may involve additional strain to fall on one joint. Treatment consists in correcting an irregular bite. If the pain is due to a true arthritis, the application of heat by an infra-red ray lamp is very helpful.

Neuritis of the great auricular nerve.—The distribution of this pain is usually in the back of the head, neck and ear. Tender spots may be felt between the mastoid and the spine, above the parietal eminence, and between the sterno-mastoid and trapezius muscles. It may arise from riding in an open motor-car or sitting near an open house window, especially in hot weather, though some authorities regard it as due to septic absorption. It usually yields to salicylates or aspirin, but heat applied by the infra-red ray lamp is very effective.

Reviews

THE ANÆMIAS.—By Janet M. Vaughan, D.M. (Oxon.), M.R.C.P. (Lond.). With notes by Hubert M. Turnbull, D.M. (Oxon.), F.R.C.P. (Lond.). 1934. Oxford University Press, London. Pp. xii plus 248, with 24 text-figures. Price, 12s. 6d.

IN the first place we must apologize for the delay brought about by a concatenation of circumstances, some avoidable, others unavoidable, in the publication of the review of this book, which, from the point of view of the general practitioner at least, is by far the most important book on anæmia that has been published for some years.

The arrangement of the book is a particularly straightforward one. The first chapter is on the normal blood picture, in the adult male, the adult female and in the child, and on normal erythropoiesis. The normal blood picture given is not a mere copy from standard textbooks, but is composed from the more recent observations reported in the literature; the authority is usually quoted.

The next chapter is on the classification of anæmias. The classification is on an ætiological basis. The three main divisions are dys hæmopoietic, post-hæmorrhagic, and hæmolytic anæmias; the first of these is subdivided into the deficiency group, the toxic group and the unexplained group, and the deficiency group is again subdivided according to the nature of the deficiency, i.e., iron, the P. A. factor, vitamin C, or thyroxin, and so on. The classification leaves only splenic anæmia and von Jaksch's anæmia unclassified. The plan seems to be a rational one and allows for regrouping when our knowledge regarding certain of the anæmias advances, without complete disorganization of the whole scheme. There is no place in this classification for a hyperchromic anæmia of pregnancy due to vitamin-B deficiency. Perhaps the author feels that the case for such an anæmia is not sufficiently

proven; many will agree with her, but nevertheless there is a hyperchromic anæmia that is cured by marmite.

The syndromes that appear in the classification are then dealt with, *seriatim*, each on the traditional plan, under the headings—definition, clinical picture, blood picture, pathological anatomy, etc. There is a short but useful bibliography, and both an authors' and a subject index.

Hæmatology is at present in a very fluid state, it would therefore be quite impossible to please everybody, but we should say that the author's compromises will have achieved the maximum success possible in this direction. The reader in the tropics will no doubt wish that she had been a little briefer in her references to the rarer anæmias and had devoted more space to the anæmias due to hookworm disease and malaria that loom so large in medical practice in the tropics. There are a few other defects that the hypercritical reader may note; for example, there are repeated references to the platelet count but nowhere, as far as we were able to see, was there any mention of what the author considers the normal count; this is important as opinions on this point differ so widely. Then, again, there is a tendency to throw in a little liver, in the treatment of conditions in which iron would have been sufficient; this will do no harm and may even increase the rapidity of recovery as liver is very nourishing, but it increases the cost of treatment very seriously.

As Professor Turnbull has contributed a very large proportion of the book, the histological and the pathological anatomy sections, which, as far as the reviewer is concerned, form the most important part of the book, one wonders why Professor Turnbull's name does not appear on the cover; we hope that this access

of modesty or of gallantry will be overcome by the time the next edition is published.

We can very strongly recommend this book to teachers of medicine as a basis for their lectures, and as we have already implied the general practitioner will find in it a valuable guide to the treatment and accurate diagnosis of all forms of anaemia. It is an Oxford Medical Publication and its format, therefore, leaves nothing to be desired.

L. E. N.

THE PREVENTIVE ASPECTS OF MEDICINE. (A Series of lectures delivered at King's College Hospital Medical School), 1934. Published by The Lancet, Limited (7, Adam Street, Adelphi), London. Pp. vi plus 376. Price, 10s. 6d.

THE general medical council, in its instructions to teaching bodies, recommends that the preventive aspects of medicine should permeate the whole curriculum. No one will question the wisdom and desirability of this dictum, but it has been very difficult of application in actual practice. The medical student during his curriculum is so much concerned with the observation of the sick and work in the hospital wards that it is very difficult for him to get the perspective of prevention until he has finished his studies. But, nevertheless, general practice is becoming more preventive in scope. People are demanding and are being taught to demand information as to modes of healthy living which the doctor should supply. This outlook should be conveyed to the student during his medical course. During 1933-34 a series of lectures was arranged by the authorities of King's College to the medical undergraduates. The lectures were given by experts in their own subjects and they were arranged methodically to cover a large number of subjects and diseases; these lectures have now been collected into a volume. Sir George Newman opens the symposium with a discourse on the development of the preventive outlook in the medical curriculum and its practice afterwards. The subjects are arranged methodically; water supply, ventilation, maternal mortality, the infant and the school child come first. Food and dietaries are next dealt with. An appropriate opening to the prevention of infectious disease is given by an admirable survey of epidemiology and its lessons by Major Greenwood. Here also is an excellent chapter on immunity by Professor Topley. The prevention of venereal diseases, accidents, and mental disorder are next dealt with and the book finishes with an account of the public agencies existing in England for the prevention of diseases.

The lectures are good and the book should be obtained by all public-health teachers and administrators. Tropical matters are of course not dealt with. We commend the book in every way.

A. D. S.

A MANUAL OF THE PRACTICE OF MEDICINE.—By A. A. Stevens, A.M., M.D. Thirteenth Edition. 1934. W. Saunders and Company, Limited, London and Philadelphia. Pp. 685. Price, 16s.

THE fact that this book has reached the thirteenth edition in forty-three years shows that there must be a demand for it. It gives, however, only the barest outlines and its only possible use would be for students performing a rapid revision the day before an examination.

It is not recommended to students in India because, to quote one example, the treatment of kala-azar is dismissed in the following manner: 'Sodium antimony tartrate is believed to have specific curative properties. One-half c.c. of a two per cent solution may be given intravenously every two or three days up to tolerance (3 to 4 c.c.)'. This antiquated and brief statement would be of no use in answering an examination question on the subject.

PHYSICAL DIAGNOSIS.—By R. C. Cabot, M.D. Eleventh Edition. 1934. Baillière, Tindall and Cox, London. Pp. xxiv plus 540, with 509 figures. Price, 22s. 6d.

IN a period of twenty years this book has passed through ten editions and the eleventh now makes its appearance. Originally written and repeatedly revised and brought up to date by one of the most famous teachers of clinical medicine in America this volume naturally contains a great deal of valuable information.

All the recent advances in mechanical aids to diagnosis such as improvements in x-ray technique and the electrocardiograph have been included in this edition, but at the same time the author is to be congratulated in clearly maintaining the importance of personal examination of the patient by inspection, auscultation and palpation, for it is very much the tendency of modern medicine to leave the diagnosis to the laboratory specialist and to rather slur over what one looked on as the old-fashioned (and accordingly inferior) methods of methodical and painstaking clinical examination. This book is full of valuable advice in the interpretation of signs, not the least useful being the explanation of certain sources of error that may arise from lack of experience.

Numerous excellent illustrations are scattered throughout the book and careful study of these without reading the text at all will be found of great educative value. The only danger in a book of this kind, in the reviewer's opinion, is that one might tend to rely on it too much, to the exclusion of one's textbooks of medicine and so become obsessed by the importance of discovering physical signs without a proper conception of their application to special diseases. But if this is borne in mind and such a book is used as an inseparable companion to a general textbook it will be found a valuable addition to the clinician's library.

To say that the book is printed and bound in the usual style of Messrs. Baillière, Tindall and Cox is sufficient recommendation regarding its manner of production.

ALLERGY IN RELATION TO LYMPHADENOMA.—By G. P. Chandler, M.D. (Camb.), M.R.C.P. 1934. John Bale, Sons and Danielsson, Limited, London. Pp. vii plus 104. Price, 10s. 6d.

IN this monograph the author has reviewed the various theories regarding the nature and aetiology of lymphadenoma; he is inclined to believe that, although the evidence is conflicting, yet it is suggestive of the disease being of an infective nature. The histological appearances of the affected glands and certain of its clinical features point towards its being an infective process. The causative organism has not been identified, but there is some evidence to suggest that it may be a filter-passing virus. The author tried to obtain evidences of the infective process by testing the allergic reactions of the patients to specific proteins of this hypothetical micro-organism. He extracted the lymphadenomatous glands by various methods and tested the patients by intradermal injections of these extracts. No allergic reactions were obtained in any of the patients. Further, no evidence of the presence of an immune body in the sera of patients was obtained by the precipitin tests. He concludes that, if any weight is to be attached to these negative findings, they suggest that lymphadenoma is of neoplastic rather than of an inflammatory nature.

D.

A PATHOLOGY OF THE EYE.—By E. Wolff, M.B., B.S. (Lond.), F.R.C.S. (Eng.). 1934. H. K. Lewis & Co., Ltd., London. Pp. x plus 283, with 124 illustrations. Price, 28s.

THIS book has been beautifully turned out by Messrs. Lewis as regards its size, binding, printing, paper and illustrations, but on perusal it hardly

lives up to its appearance. The author has bravely undertaken to introduce a subject whose essentials 'most students and ophthalmic surgeons find difficult to come by'. This introduction is somewhat abrupt and to the reader rather suggestive of an illustrated nomenclature of diseases. Over a fifth of the illustrations are of normal anatomy from a previous work by the author. The ordinary elementary volume which appears periodically in connection with English clinical ophthalmology usually escapes a severely critical review because many critics have come to regard such publications as part of a custom. In view of the basic importance of pathology, however, an author of some experience who produces an expensive, though elementary book, can hardly expect to escape, nor would he be flattered by faint praise. In the present volume the sins of omission are many, and those of commission not a few. Some examples of these may be given.

Page 101. We find 'the vitreous is entirely inert to trauma'. This is unfortunately not true.

Page 103. Synchysis scintillans:—No mention is made of asteroid hyalitis.

Page 124. 'Retinitis pigmentosa sine pigmento is probably an early stage of retinitis pigmentosa'; surely not.

Page 167. 'Colobomata result as a rule from imperfect closure of the foetal fissure'. This is a doubtful statement, and recent views are not given.

Page 190. Glioma is 'the commonest cause of sub-acute glaucoma in children'. This is certainly not true in India.

Page 201. Syphilis of the optic nerve:—No idea of the frequency of this condition is given, the same is true of other conditions throughout the book.

Page 223. Under lymphoma of the orbit it is mentioned that 'leukæmic and pseudo-leukæmic tumours occur'. Lymphoma is one of the commonest tumours of the orbit in some countries.

Page 241. Iritis is 'not common' in diabetic eyes. Such a statement is very questionable if biomicroscopic methods are used.

Pages 259 and 260. Rodent ulcer:—There seems to be some confusion between true rodent ulcer and the common basic epithelioma of the orbital region.

There is some lack of perspective in dealing at relatively great length with some subjects, e.g., papilloedema, sarcoma of the choroid, whilst treating others with actual brevity, e.g., the sclera and glaucoma.

References in the text to the literature are scanty and the bibliography, largely German, omits many important references in English.

The Indian student will probably find the pathology in his textbook by Fuchs more satisfying, and what the specialist wants is a new edition of Parson's *Pathology of the Eye*, or a modern work arranged on as excellent a pattern, but this work will help the post-graduate student to an orderly arrangement of his ideas.

R. E. W.

SCHISTOSOMIASIS (BILHARZIASIS).—By Dr. R. Girges. 1934. John Bale, Sons and Danielsson, Ltd., London. Pp. xii plus 529. Illustrated. Price, 25s.

This book represents an enormous amount of work and it includes everything of importance that is known of human schistosome infections. The first chapter is devoted to a detailed history of the three infections, this is followed by full anatomical descriptions of the three species and their relations with animal schistosomes. The epidemiology and distribution throughout the world are fully detailed in part III, and part IV consists of a complete description as

to how to collect and study material, both adult and larval, as well as giving useful descriptions of the chief snail carriers of the infections. The diseases caused by *S. hæmatobium* and *S. mansoni* are naturally given in more detail than that caused by *S. japonicum* for the author has had to copy from other works for a description of this disease; in this he has obviously freely borrowed from the excellent account given by Faust and Meleney some years ago.

Over one hundred pages are devoted to what the author has described as the visceral type of *S. mansoni* infection. It is very largely his work that has been responsible for the recognition of this form of schistosomiasis and he has collected in this book a great deal of epidemiological, clinical, and pathological data to establish this as a disease. It is unfortunate that in the ætiology his enthusiasm has led him to state what are only probabilities as definite facts.

The reviewer gives full credit to the author for producing a book in a foreign language and such a difficult one as English at that. But he cannot help expressing regret that someone with a critical discrimination was not asked to edit it, for an otherwise fine piece of work is marred on practically every page by the author's insufficient knowledge of English. It is also considered an unjustifiable extension of the principle of naming helminthic diseases after the causal parasites to refer to *Schistosoma mansoni* infection as 'mansoniæsis'.

P. A. M.

AIDS TO THE ANALYSIS OF FOOD AND DRUGS.—

By C. G. Moor, M.A. (Cantab.), F.I.C., and W. Partridge, F.I.C. Fifth Edition. Revised by J. R. Nicholls, B.Sc. (Lond.), F.I.C. 1934. Baillière, Tindall and Cox, London. Pp. viii plus 322. Price, 5s.

THE phrase 'adulteration of foods' should nowadays be somewhat extended; the terms sophistication and fortification of foodstuffs must, in the light of recent knowledge, be introduced. The public little realize how many of their purchased foods are altered for better or for worse in order to improve their appearance, taste or saleable value. A detailed list of the various substances added to foods and drugs cannot be given in a review, but a perusal of the pages of this book is enlightening. A description of the method for estimating vitamin C shows that manufacturers advertise rather than conceal the contents and/or supplements of their wares. Many of these fortifications are indirectly the results of the increased knowledge and interest taken by the public in the newer science of nutrition. It behoves the medical profession to see that manufacturers do not exploit or misrepresent such knowledge to the public. The book is an excellent small summary of the various methods for estimating a number of food adulterants and additions.

H. E. C. W.

SURGICAL APPLIED ANATOMY.—By Sir Frederick Treves, Bart., and Revised by C. C. Choyce, C.M.G., C.B.E., B.Sc., M.D. (Edin.), F.R.C.S. Ninth Edition. 1934. Published by Cassell and Co., Ltd., London. Pp. x plus 720, with 174 figures including 66 in colour. Price, 14s.

A NEW edition of a medical classic is always welcome. Few medical books have the distinction of having successively passed through the capable hands of such eminent authors as the late Sir Frederick Treves, Sir Arthur Keith and Professor Choyce. Consequently, this book gives a presentation of facts and their application, such as is not to be found in the same collected form elsewhere. It is written in a very pleasant style, in fact it is a treatise on the living anatomy.

The book, based on regional anatomy, is subdivided into six parts, the last being devoted to the spine and the spinal cord. As to the general plan, adopted by the author, the anatomy of the region or organ is first described and then the surgical application is discussed very fully. In this way, a great deal of surgical matter and pertinent pathology have been incorporated. The notes on development and embryological anomalies are, everywhere, clear and succinct. To choose at random—the description of radiological anatomy of the cranium is excellent. The subject of lymphatic drainage of important organs, like the tongue and the breast, have been very fully dealt with. The chapter on hernia is particularly good, but it is regrettable that sufficient emphasis has not been laid on the fact that, in the vast majority of cases of the oblique indirect inguinal hernia, the sac or a peritoneal diverticulum is of congenital origin, owing to the patency or non-obliteration of the processus vaginalis. The illustrations are numerous and, though not of such artistic merit as one might wish for, are adequate and based on various authoritative contributions. One minor criticism may be offered; if the usual colour scheme of red for the arteries, blue for the veins and green for the lymphatics were adopted, the value of the illustrations would have been considerably enhanced. It is a minor defect and may be easily rectified in the next edition. It is a book, which may be regarded as indispensable and we commend it to all senior students and teachers of anatomy and surgery.

An adequate index is appended.

P. N. R.

SYNOPSIS OF SURGICAL ANATOMY.—By Alexander Lee MacGregor, M.Ch. (Edn.), F.R.C.S. (Eng.). Second Edition. 1934. John Wright & Sons Ltd., Bristol. Pp. xx plus 644. Illustrated with 639 figures. Price, 17s. 6d. net

THIS book may be acclaimed, without the least hesitation, as a masterpiece of its kind. The very fact that a new edition has been called for within such a brief period of its publication bears eloquent testimony to its worth and utility. The outline of the book is original in conception and so is its method of treatment of the subject-matter. It is subdivided into two parts, namely, the anatomy of the normal and that of the abnormal. The former consists of thirty-one chapters, dealing with all the important organs and with the different systems. A special chapter has been devoted to the anatomy of the child.

The first part is only excelled by the second half of the book, which contains sixteen chapters. The anatomy of congenital errors is considered first and it is followed by such diverse subjects as the anatomy of nerve injuries, bodily habitus, stiff joints and the sphincters. Other noteworthy chapters include the anatomical basis of clinical tests, surgery of the lymphatics and selected pathological anatomy. The difficult subject of the sympathetic nervous system has been described with a precision and lucidity which are seldom met with even in the special monographs. It is hardly possible in a brief review to do full justice to the comprehensive nature of this encyclopædian work. Important references have been mentioned, as a rule, in the footnotes.

This book is illustrated with 639 figures of unusual variety and excellence. There are only a few, like those of the hypospadias and extroversion of the bladder, which might be replaced in the next edition with better ones. The printing and get-up are excellent. An exhaustive index has been appended. We warmly endorse the verdict of Sir Harold Stiles that this book supplies a real want and will be welcomed alike by the student, the surgeon and the teacher of surgery.

P. N. R.

EXPERIMENTAL PHYSIOLOGY FOR MEDICAL STUDENTS.—By D. T. Harris, M.D., D.Sc., F.Inst.P. Second Edition. 1934. J. and A. Churchill, Limited, London. Pp. ix plus 248, with 230 illustrations and plate in colour. Price, 12s. 6d.

THERE can be no question of the importance of a good theoretical and practical course of physiology for medical students. This book is intended to supply such with special reference to human physiology. At the outset it might be said that the experiments described and the appended course are for most laboratories an ideal to be aimed at. The refined and indeed time-robbing technique demanded in certain branches of modern physiology are well known, notably in hydrogen-ion concentration work, electro-physiology, and the estimation of blood gases. To lay too great stress on such work on isolated organs would tend to narrow the student's mind and render him incapable of interpreting the organism as a whole when he comes to the bedside. Experiments capable of being carried out by and on the student himself are given—to mention one innovation in chapter XIII on the movement of water. This type of experiment and the usual ones on the cardiovascular system are essential. In general, Prof. Harris seems to have succeeded in retaining what is essential in the older methods while introducing the new. A student who has carried out most of the experiments and has a good grasp of the theoretical principles should be well trained for appraising signs and symptoms in the patient. The book is well written and the details and diagrams clearly set out. It should be strongly recommended to those desiring to build up a first-class course in physiology for medical and indeed science students.

H. E. C. W.

THE PHYSIOLOGY OF HUMAN PERSPIRATION.—By Yas Kuno. 1934. J. and A. Churchill, Limited, London. Pp. x plus 268, with 38 illustrations. Price, 12s. 6d.

THE author in this monograph has tried to explain many different problems regarding human perspiration. References have been made of numerous other writers working on the different aspects of the subject and the author, by a short discussion, has attempted to come to a definite conclusion. The book is full of interesting information and many experiments have been described which are of great practical value. An useful perspiration chamber and a portable apparatus for the measurement of perspiration have been described. The monograph will be of great help to the research workers in this subject. The bibliography at the end of the book will be found very useful.

P. D.

AIDS TO EMBRYOLOGY.—By Richard H. Hunter, M.D., M.Ch., Ph.D., M.R.I.A. Second Edition. 1934. Baillière, Tindall and Cox, London. Pp. viii plus 172, with 39 figures. Price, 3s. 6d.

THE author in this little book of 12 chapters has embodied in a nutshell the important points about the development of the different organs of the body. It has been written in an easy style and the subject-matter has been clearly put. The commoner abnormalities of development have been appropriately arranged and placed at the end of the chapters. The summaries of the development will be of great help to students for quick reference. The book has been made up to date by the incorporation of short notes on the development of the carotid sinus and of the recent ideas about the development of the face, the thyroid gland and the branchial sinuses. The diagrams are clear and descriptive. It is hoped that the book will be of great help to students in medicine preparing for their examination.

Abstracts from Reports

ANNUAL REPORT OF THE PUBLIC HEALTH COMMISSIONER WITH THE GOVERNMENT OF INDIA FOR 1932

VOLUME I

SECTION I

ON THE STATE OF THE PUBLIC HEALTH IN BRITISH INDIA AND SOME INDIAN STATES

Introduction

CERTAIN features of India's health problems demand urgent attention and, as far as possible, these have been commented upon frankly. Their urgency demands plain speaking, for, in the hurly-burly of the present-day world, politicians and the people they represent alike are in danger of forgetting, if they ever knew, that without health other things are as 'dust and ashes'. No apology is made for what may seem to be hyperbole; the scientifically-trained mind abhors exaggeration as nature abhors a vacuum, and if the reader on occasion should at the first glance consider certain statements unduly stressed, he must reconsider that impression in the light of the facts given in the course of this report.

The question of the organization and functions of the public health department required by the central Government of India has been mooted on many previous occasions and it seems only natural that on the eve of new constitutional reforms this subject should be uppermost in the mind of the public health adviser to the Government of India and should find a place in the preliminary paragraphs of his report. Under existing arrangements, all public health questions which come before the Government of India—and these questions are not few in spite of public health being a 'transferred' subject—are dealt with by the Public Health Commissioner alone, on whose shoulders have also been placed the administrative duties involved in the secretaryship of the Indian Research Fund Association, a body which corresponds in function to the Medical Research Council in England. The latter duties include not only administrative work but also the financial control of every item of expenditure incurred in every research enquiry conducted under the auspices of the Research Fund Association. These responsibilities, formerly carried out by an assistant director-general (sanitary) and for a time by the director of medical research, debar the Public Health Commissioner from devoting due time to the real functions of his office. Certainly drastic modification of the situation is required if the central government under the new constitution is to have a suitable public health organization, not only capable of advising on the numerous public health problems for which the new federal government will be directly responsible but capable of initiating fresh developments and of planning improvements. For the health and welfare of the peoples of India are the most important problems with which the new governments—federal and provincial—will be faced almost as soon as they are brought into being. By some that statement may be looked upon as an exaggeration; it is, on the contrary, a plain statement of fact made without any suggestion of personal or departmental aggrandisement. It is one moreover which is becoming more and more evident to those who have examined actual figures and who have the vision to realize their implications. Here are some of those figures. The population of British India according to the census of 1931 was 271,526,933; that of India as a whole 352,837,778. The rate of increase during the decennium 1921–31 was no less than 10.6 per cent which means that during these

10 years the population increased by nearly 34 millions. Various competent authorities have expressed the opinion that this rate of increase may be taken as the normal in the absence of any catastrophic occurrence like the influenza epidemic of 1918. At the time of writing, more than three years have passed since the last census and during these years the usual epidemic diseases, cholera, plague and smallpox, have all shown large decreases in incidence, whilst famine, in its death-dealing form at least, has been unknown. Since the end of February 1931, therefore, nearly 13 millions have been added to the population of India and the total must now be approximately 365 millions. On the assumption that existing conditions will continue, by 1941 when the next census is due to be taken, the population will probably be found to exceed 400 millions or nearly 50 million persons more than in 1931. Several authorities have expressed the opinion that many of the provinces of India are already overcrowded and Mr. Wattal in his recent volume 'The population problem in India' gives official figures in support. Where are those additional 50 millions of people to find bread? How are the adult survivors later on to find employment? Can improved methods of agriculture and the extension of cultivation to unused land provide the additional food supplies required? These questions are of immediate importance and will necessarily confront the Government of India within the next few years. But others are equally pressing, and, in inviting attention to those, I cannot do better than quote from a recent pronouncement made by Major-General Sir Robert McCarrison, Director of Nutritional Research in India, in his introduction to an article on 'Dietetics: Food and Race' published by Professor Kanga of Ahmedabad. He writes:

'It is apt to be forgotten that the well-being of a people depends more on proper nutrition and efficient sanitation than aught else. The proper nutrition of her people, the adjustment of the food supply to the population and of the population to the food supply, the provision of efficient sanitation in her towns and villages: these are India's needs; all else is of secondary importance'.

'My own concern has been mainly with nutrition; and my researches have led me to the conclusion that the diet of many millions of the Indian people is not such as can maintain physical efficiency and health. They are condemned, from their mothers' wombs, to a subnormal or diseased existence as certainly as is the engine of the best motor car when not provided with efficient lubrication or when supplied with an improper fuel. Intestinal disease, kidney disease, pancreatic disease, stone in the bladder, beriberi, epidemic dropsy, malnutrition, oedema, anæmias, scurvy, rickets, osteomalacia, pellagra, lathyrism, disorders of pregnancy, keratomalacia, night blindness, tetany, dental caries, and, above all, greatly increased susceptibility to infectious diseases; all these, and more, have been shown to be directly or indirectly due to faulty nutrition. Surely a matter of such moment is the concern of every person of education, influence or wealth, of every employer of labour, of every humanist'.

What can be done about it? How are additional and improved food supplies to be obtained? How is the general standard of living to be raised? Major-General Sir John Megaw, late Director-General, I.M.S., and others have written of the gloomy outlook for the future 'not only for the masses of the people who must face an intensified struggle for bare subsistence but also for the upper classes whose incomes depend on the production of a surplus of crops and other commodities'. The suggestion has been made that, in order to review the situation before India reaches disaster, a commission of experts should be appointed to examine every aspect of economic life of India, to make an accurate survey of the present position and a reliable forecast for the future. This is no place to discuss in detail the measures which are

required; these must necessarily include energetic steps for the prevention of disease and equally energetic measures for the education of the people in regard to mastery over environment. But there can be no doubt that the circumstances are such as demand the urgent attention of both central and provincial governments and a wide development of both central and provincial public health departments manned by experts capable of advising on the many difficult health problems which confront the leaders of this country. On the interpretation of these problems and on the lines of action adopted for their solution will depend the prosperity, health and welfare of many generations yet unborn.

Weather conditions.—Taking the year as a whole, rainfall over the country was within 20 per cent of the normal in all subdivisions except Mysore where there was an excess of 32 per cent. The main feature of the cold weather months was the unusually northerly course of most of the western disturbances during January resulting in scanty precipitation in the plains of N. W. India. During January and February, total rainfall was in large excess in Hyderabad and Mysore; in moderate excess in Burma; normal in Assam, in N. W. F. P. and in Madras Presidency; and in moderate or large defect elsewhere. Over the plains of India as a whole, the average rainfall of this period was in defect by 34 per cent. The unusual northerly course of the western disturbances was also responsible for mild winter conditions in N. W. India and its neighbourhood.

Famine conditions and their relief.—The test works which were in operation in Assam, Bengal, Burma and the C. P. during the previous year continued during 1932-33. Those in Assam were closed down at the end of May and cost only Rs. 11,330. In Bengal, distress continued till the end of September in the Rangpur, Bogra, Pabna and Mymensingh districts. In Burma, scarcity relief operations were in progress in 8 or 9 districts. By the middle of June conditions had improved and although it was hoped to close the works by July, conditions in the districts of Prome and Thayetmyo necessitated their continuance. Relief works were in progress in the Prome and Yamethin districts but operations since the middle of July were on a more restricted scale. In the C. P. and Berar test works were in progress from March to the end of July in parts of the Buldana, Yeotmal, Amraoti and Akola districts.

In Madras, conditions in the east of Bellary district, a tract frequently subject to drought, had been causing anxiety since November 1931, and road works under the control of the district board were started early in the year. The local government opened test works in order to determine the necessity of providing relief under the Famine Code. Gratuitous relief was at first provided for dependants of the workers, but this was discontinued in June and the works were closed at the end of September. Relief to the agriculturists of the affected area was also provided in the shape of suspension of land revenue and distribution of agricultural loans.

Hissar district in the Punjab, which has frequently been subject to visitations of famine, again suffered from scarcity of food and fodder during 1932-33 and test relief works were opened at the beginning of January 1933. Road works under the district board were also in progress. A private relief committee did useful work, mainly in the form of distributing cotton and wool for spinning in the affected villages.

LIVE BIRTHS

British India.—Live births registered during 1932 numbered 81,384 less than the figure for 1931. The highest rate was recorded in the Central Provinces and the lowest in Bengal and in Coorg.

Infant mortality.—Twenty-six per cent of the total mortality occurred during the first year of life, against

25 per cent in 1931. In England and Wales the corresponding figures for 1931 and 1932 were 9 per cent and 8 per cent respectively. Compared with 1931 the rate of 168.7 for British India was lower by 10 per mille.

Causes of infantile mortality.—Statistics of causes of infantile mortality are not yet recorded in India but there is every reason to believe that the main causes are prematurity, infantile debility, bowel disorders, convulsions, malnutrition, diarrhoea and enteritis, respiratory diseases, inanition, smallpox, fevers and marasmus.

Registration.—Bengal is the only province in which registration of births and deaths is compulsory in all urban and rural areas. In Madras Presidency, the Births and Deaths Registration Act (Act III of 1899) was further extended. In rural towns, registration still continues to be badly done, but the compilation of statistics for non-municipal areas was centralized in the office of the D. P. H. and improvement should occur. In Bihar and Orissa, registration is compulsory in all the 58 municipalities but not in rural areas; the police is the reporting agency throughout the province. In Burma, registration was in force in 32,478 villages and towns. In the Arakan Hill Tracts, Chin Hills and in some parts of Shan States, registration has to be carried out by means of tallies made of coloured sticks or notched bamboo splits, whilst illiterate registrars and poor means of communication increase the difficulties. In Assam, registration is compulsory in the towns, but not in rural areas. In the latter, *chowkiars* and *gaonbaras* carry out this work in addition to their other village duties.

[This report contains a great deal too much important matter for adequate abstraction in a single issue of the Gazette, so it is proposed to give abstracts from section two, which deals with diseases, in our next number.—EDITOR, I.M.G.]

THE ROCKEFELLER FOUNDATION: ANNUAL REPORT FOR 1933

International Health Division

From the time of its establishment in 1913 the Rockefeller Foundation has engaged in public health work. At the outset it took over the work of the Rockefeller Sanitary Commission, which had been chiefly directed toward the relief and control of hookworm disease. From hookworm disease, the Foundation research and control activities have been extended to other diseases, such as malaria and yellow fever. There has been, however, no attempt to cover in any intensive manner the entire field of public health. A selection is made and, within the spheres selected, limited and practical programmes adapted to local situations in many parts of the world are developed.

Attention to communicable diseases has led to the support of various other activities essential to the development of progressive public health programmes. A particular effort has been made to further public health education. Aid has been given toward the establishment and maintenance, at strategic world centres, of postgraduate schools of hygiene and public health of university grade. The upkeep of a supply of highly-trained workers in the public health field has been aided also by a liberal provision of fellowships. An extensive fellowship programme has been in operation since 1917.

Yellow fever

The yellow fever work in which the Rockefeller Foundation has for some years been engaged took another important step forward in 1933 by the completion, in co-operation with various governments, of an extensive survey which disclosed with a considerable degree of definiteness the areas in Africa where the disease occurs. Such a survey was one of the main

objects in establishing in Lagos, Nigeria, eight years ago, a field laboratory for the study of yellow fever.

Delimitation of endemic areas of yellow fever became possible only after much preliminary work in the field and laboratory, in the course of which the susceptibility of the *Macacus rhesus* monkey and the white mouse to yellow fever was demonstrated and a procedure known as the protection test was developed. A person who has once had yellow fever does not, so far as is known, contract the disease again. The blood of such a person furnishes him protection from yellow fever for the rest of his life; and when, under suitable conditions, the serum from his blood is injected into monkeys and mice that are susceptible to the disease, it protects them also.

For the protection test, blood serum from the person under investigation is injected, together with the yellow fever virus, into healthy mice. If the mice survive, this is evidence that the person furnishing the serum has at some time in the past had yellow fever. The death of the mice indicates that the person has not had yellow fever. Thus the test is used to study the distribution of immunity to yellow fever. Such immunity corresponds to the previous distribution of the disease during the lifetime of the individuals tested. The last appearance of yellow fever in a community can be gauged by collecting blood specimens from persons of the younger age groups.

With the discovery of the susceptibility of the *Macacus rhesus* and the mouse to the virus of yellow fever has passed the need for human volunteers for experimental purposes which existed at the time of those first great successful yellow fever studies carried out in Cuba in 1900 and 1901 by Major Walter Reed, of the United States Army, and his associates.

Epidemiology.—The extensive study of the epidemiology of yellow fever has brought to light some fundamental aspects of yellow fever previously unknown. Formerly the disease was considered above all a violent scourge of seaports. Even after Reed had incriminated the mosquito as the vector, and as late as 1920, the clinical and epidemiological picture of yellow fever accepted almost everywhere was a simple one.

The severe type of the disease was considered typical. It was thought to be an essentially urban malady, transmitted by a single *stegomyia* mosquito, *Aedes aegypti*. The key to control was believed to be the cleaning up of cities. By this method conspicuous success was obtained in banishing yellow fever from the seaports of North America, certain parts of South America, the West Indies, and the Panama Canal. But the disease did not disappear entirely, and we now know the reason why. Yellow fever may occur in the form of a mild disease native to interior populations. It has been found to be much more widespread than is indicated by reported outbreaks. It can exist for years as a rural malady and may occur even in places where the *stegomyia* mosquito is not found. This means that other mosquitoes can carry it, although the *stegomyia* is undoubtedly the main culprit. The control of yellow fever in large coastal towns is not sufficient to cause the disease to die out within a reasonable length of time in countries where it is indigenous.

Since 1931 the Foundation has, with the co-operation of many governments, been carrying on careful investigation of the distribution of yellow fever, by collecting blood specimens, at random, from healthy persons who had lived all their lives in the localities under investigation, and testing these for their power to protect mice against injections of yellow fever virus.

The areas throughout the world in which evidences of recent yellow fever have been found are much larger than would have been expected from known experiences with the disease.

Because of the somewhat startling findings, the specificity of the protection test has been questioned.

Control tests were made with human sera from countries believed to have been entirely free from yellow fever for generations. Among 423 specimens from such regions, three (0.7 per cent) gave the wrong indication. These misleading results of less than 1 per cent were doubtless due to several sources of error. To all intents and purposes, however, the testing of this large number of specimens confirmed the reliability of the results being obtained in other regions.

The results of the mouse protection tests showed that, in West Africa proper, yellow fever is more prevalent than was previously supposed. Approximately 25 per cent of all sera examined gave positive results. Practically the entire area covered by the survey was shown to be infectible. The Sahara Desert, however, forms an effective barrier against the disease on the north.

Findings confirm the opinion previously held that an endemic area of yellow fever exists in south-western Nigeria. It was not possible definitely to exclude endemicity in other parts of this colony, but meteorological conditions in northern Nigeria would seem to be unfavourable to the permanent existence of the disease.

Protection tests in various age groups in cities in the endemic area of Nigeria show that in endemic centres yellow fever is not confined to children, but that the percentage of those who have had the disease increases gradually up to old age. Some persons escape infection throughout life.

In the colonies to the south and south-east of West Africa, except in the interior of French Equatorial Africa, percentages of positive sera were much lower than those found in the colonies of West Africa proper. This is because the conditions in the former region are relatively unfavourable to the maintenance of yellow fever infection.

In French Equatorial Africa, where yellow fever had never been reported, 18.4 per cent of the blood specimens collected in thirty-seven towns along the coastal area and in the interior protected mice against yellow fever virus. The high percentages of protective sera obtained from both children and adults in the interior towns indicate that yellow fever has been widespread within recent years, as well as in the past. Apparently no barrier against the invasion of the disease toward the east exists in this region. The findings in the coastal area of this colony show that although some yellow fever has been present there in the past, almost no cases have occurred during recent years. The practically negative findings in the southern and south-eastern portions of the Belgian Congo and throughout the whole of Angola suggest that the limits of yellow fever invasion in these directions have been reached.

Vaccine.—Vaccination against yellow fever by the injection of human immune serum and living yellow fever virus fixed for mice was begun in 1931. The number of persons vaccinated in the laboratories of the Rockefeller Foundation has now reached fifty-six. This method of vaccination cannot be applied as widely as is desirable on account of the difficulty of securing the required amount of human immune serum, which, of course, must be obtained from persons who have had yellow fever or have been vaccinated against the disease.

Vaccination has been successful. Reaction, when present, has consisted of a rise in temperature about thirty-six hours after the injection of the virus, often accompanied by headache and sometimes by generalized discomfort. In order to obtain information as to the duration of immunity in vaccinated persons, sera from eleven of these were tested two years after vaccination. In every case evidence of protective power of the serum was obtained, but in most instances the titre or potency was found to be below the level reached soon after vaccination. Four persons with low titres were given intradermal injection of some of the virus preparation used in vaccination, with the

usual injection of immune serum omitted. The immune serum was unnecessary because protective antibodies were already present from the former vaccination. The titres rose rapidly after the injection, and in two instances reached their former high level. From this it appears that revaccination can be performed simply and effectively if found advisable. More time will have to elapse before a definite opinion with regard to the need for revaccination can be formulated.

So far as is known, no person vaccinated against yellow fever has contracted the disease. There have been no cases of yellow fever among the Foundation staff either in the laboratory or in the field since vaccination was begun two and a half years ago, although accidental infections had previously been frequent and seemingly unavoidable.

In experiments carried out during the year, it was found that immune serum recovered from animals, when injected into monkeys twenty-four to forty-eight hours after they had been inoculated with yellow fever virus, was capable of preventing or ameliorating the disease in a significant proportion of the monkeys. After forty-eight hours the effect was less definite. In no instance did the monkey recover if the administration of serum was delayed until his temperature had reached 104°F. This temperature is the threshold of fever and the beginning of illness in rhesus monkeys. Experiments show that there is no virtue in administering immune serum therapeutically. The serum, in other words, can be used only as a preventive and not as a cure.

Virus studies.—Filtrable viruses can be cultivated in tissue cultures outside of the body. In the absence of living cells or when tissue extracts alone were used, survival of the virus for a limited time could be obtained, but propagation under these circumstances was not possible. In the presence of dead tissue the virulence of the virus cultures disappeared.

A special study was made of two strains of mouse-adapted yellow fever virus in tissue culture, which had been cultivated through more than one hundred generations without change in pathogenicity, in a medium consisting of diluted normal monkey serum and living chicken embryo cells. Culture virus contained in this medium may be kept virulent for more than half a year if dried when in a frozen state. Virus which has entered into the living cell in the culture medium is not acted upon by immune serum. Virus in dead cells is destroyed under these conditions.

Investigations were made to discover whether the sera of baby monkeys born of mothers immune to yellow fever would display any protective properties against the disease. It was found that the sera of five monkeys less than six months old, born of such mothers, did display protective properties. Sera of two of these monkeys, when tested three months later, showed no protective power. It is not determined whether the protective properties of the sera of the baby monkeys were derived from the mother through the placenta or by way of the maternal milk. There is a possibility that in very young children there may be present a temporary immunity to yellow fever transmitted from the mother.

Since the virus of yellow fever is filtrable, it would be interesting to know just how small or how large the particles are that pass through the filters. During 1933 some preliminary work was done on this problem.

Studies of mosquitoes.—Two experiments are reported in which virus was transmitted to rhesus monkeys by the bites of *Culex fatigans*. In one experiment the extrinsic incubation period was seventeen days; in the other it was twenty to twenty-three days. In one lot of mosquitoes survival of the virus was demonstrated as late as thirty-nine days after the meal on infective blood. The evidence indicates that a great many mosquitoes in the experimental lots were able to free themselves of the virus. It is concluded

that *Culex fatigans* is not an efficient host of yellow fever virus.

Malaria work

During 1933 the states of the United States receiving aid were Florida, Georgia and Mississippi. The foreign countries in which assistance was given were Jamaica, Puerto Rico, Costa Rica, Nicaragua, Panama, Colombia, Venezuela, Albania, Bulgaria, Germany, Greece, Italy, the Netherlands, Portugal, Spain, India, and the Philippine Islands.

As a rule a country or state is not aided in dealing with its complete malaria problem. In the case of such a widespread disease as malaria, the problem of successful control, especially in the tropics, is one that requires years of gradual effort by the people and the governments themselves.

At Durres, in Albania, a distinct success was achieved in the control of the malaria vector (*Anopheles maculipennis chutus*) by the salinification of a lagoon in which it bred in large numbers. This mosquito is of a type that does not breed in salt water, and by rendering its favourite breeding place salty, the problem of its control was solved. Such an expedient happened to be possible in this particular area and is an illustration of the strictly local and sometimes unique measures that may be employed in malaria prevention.

An occurrence at Mysore City, in India, illustrates the dangers that sometimes attend irrigation projects. After the completion of a new dam there in connection with the installation of a hydro-electric plant, malaria began to spread. In the area concerned there were a thousand deaths from this disease. Here we have an example of man-made malaria, usually controlled with comparative ease, but illustrative of the principle that in drainage projects the possibility of furthering instead of hindering mosquito breeding must be taken into account. In Bangalore, the chief city of the state of Mysore, the malaria carrier, *A. stephensi*, has been controlled at low cost by the use of the small top-feeding minnow known as *Gambusia*.

The problem of tropical malaria is well illustrated by the work in the Philippines. At the Stotsenburg Army Reservation Camp, where malaria has defied all efforts since 1903, it is finally coming under control through army work based on studies, made in association with the Foundation, of the breeding habits of the mosquito (*Anopheles funestus-minimus*, subgroup of King) chiefly responsible for the transmission of the disease. It has been found that this mosquito is one that breeds almost entirely in streams. Accordingly, a Paris green distributor motivated by the water current has been devised. By dropping the larvicidal mixture from a mechanical device on to the surface of the stream, so that it is spread by the stream itself, the cost of malaria control has been considerably reduced. Well-planned drainage measures are also employed. For the Philippines as a whole, emphasis is placed on the use of bed nets. Tropical houses are not always of sufficiently strong and exact construction to make screening effective, but bed nets can be used with great success. The problem was studied and specific recommendations were made regarding material for these nets, their size, and the method of using them.

Mosquito studies and surveys.—A study was made of the flight range of the *funestus-minimus* subgroup of anophelines in the Philippines. Stained mosquitoes were liberated and recovered at distances varying from 1 kilometre to 1½ kilometres from the point of liberation. It is concluded that these anophelines fly a distance of at least 1 kilometre.

A new type of trap for catching adult mosquitoes was developed in the Philippines. It consists of an earth-lined box imitating the natural daytime resting places favoured by the chief local vectors of malaria.

A study was made of the possible value of an animal

barrier in malaria control in the Philippines. There is strong presumptive information that mosquitoes which had first taken blood from an infected human being were attracted to carabaos for a subsequent feeding at a time when they were potentially dangerous to man. This might indicate the possible usefulness of an animal barrier. It is concluded, however, that when these animal barriers are uncontrolled, they are of little use.

Malaria surveys.—Although malaria has been known to exist in various parts of Mysore State, India, for a long time, no extensive study of the disease was undertaken up to 1927. In that year a rapid survey was made to determine the amount of spleen enlargement in children. Following this survey it was decided to select three representative areas for more intensive study. In these areas an effort was made first to discover the seasonal variation of malaria. Then many other aspects of the malaria problem were studied *seriatim*, and the results were published in a number of papers.

A survey of anophelines revealed twenty-two species, of which thirteen had been previously recorded. Many thousands of these anophelines were dissected. Infection was reported in *A. culicifacies* and *A. stephensi*. A study was made of the relative frequency of the occurrence of the parasites of benign tertian, malignant tertian, and quartan malaria. Spleen and parasite relationships were carefully gone into, especially so far as age groups are concerned. These studies comprise the subject-matter of the first three papers.

A fourth paper deals with experimental control of malaria with Paris green. A fifth describes the control of anopheline breeding in Bangalore City, and goes further into the matter of malaria prevention by means of Paris green, which successfully controls *A. culicifacies* breeding. *A. stephensi*, which breeds in wells, was combated by stocking these wells with small fish. All the wells of Bangalore City were thus treated. The costs were kept low, well under 1 per cent of the normal receipts of the municipality.

In a sixth study, hemoglobin estimates made in the three research stations before control work began are discussed, with reference to sex and age. A seventh paper gives more detailed information on the anopheline transmitters of malaria. *A. culicifacies* and *A. fluviatilis* are apparently the most important malaria vectors of the rural areas of Mysore, and *A. stephensi* and *A. varuna* are the minor carriers.

Experimental studies

Nine 'howler' monkeys were successfully inoculated with parasites from man, and one through subinoculation from another monkey. The longest infection lasted eight days. It is suggested that *P. falciparum* may be so poorly adapted to this abnormal host that it is largely self-limited and requires little resistance on the part of the host. *P. falciparum* can be overcome and eliminated by natural processes much more easily than *P. brasilianum*, the common parasite of the monkey. However, it should be noted that the reaction of the monkey to a large number of trophozoites injected intravenously does not completely answer the question of susceptibility. The susceptibility of monkeys to human malaria is of epidemiological importance; and from this epidemiological standpoint, not blood inoculation, but the use of anophelines infected with human malaria is the critical test.

Hookworm disease

A study was made of the racial and age group incidence of the common intestinal helminths among Malays, Chinese, and Indians in the Straits Settlements. The study was based on data obtained during a survey made between 1925 and 1928, comprising 27,000 examinations. The incidence rates for hookworms, roundworms and whipworms were higher in Malays than in Chinese or Indians. Chinese have the lowest incidence rates in all age groups for hookworms

and roundworms, but the incidence of whipworms tends to be significantly higher in the Chinese than in the Indians. Hookworm infection among the three races tends to become greater in the older age groups. Roundworm and whipworm infections tend at first to rise and then to fall as the age increases, regardless of race. Conditions at the present time are possibly very different from those prevailing when the survey was made, because of the thousands of sanitary latrines installed since then.

On the basis of data obtained by experimental infection of dogs with the common dog hookworm, *Ancylostoma caninum*, a special study was made of the nature and cause of hookworm anaemia. It was concluded that it is not necessary to postulate a toxin to account for the anaemia of hookworm. The anaemia is of the type which is clinically associated with chronic hæmorrhage. It responds well to iron therapy.

The anthelmintic properties of certain alkyl phenols were investigated. In the search for a safe and effective human ascaricide, some 500 substances were tested. Hexylresorcinol was found to have as great activity as any. It is a safe and effective remedy for ascariis, and it is also relatively effective against hookworm disease. There were no cases of intoxication from this drug when it was properly administered, but there were reports of local irritation at the mouth caused by hexylresorcinol pills. Attempts were made to overcome the irritant properties of the drug. Ordinary methods failed, and a study was therefore made of several series of related compounds, alkyl phenols. None of these were as effective as hexylresorcinol however, and it appears doubtful whether a drug will be found in this series of compounds which will be as active as hexylresorcinol and yet have no local irritant action. For uncomplicated hookworm disease tetrachlorethylene is, according to present knowledge, the best drug available.

A group infestation of seven cases of acute hookworm disease occurring in Puerto Rico was reported. The infection was contracted during sea bathing in water highly polluted from a rain-swollen overflowing stream. There was sudden onset of symptoms, which included initial dermatitis followed by marked throat discomfort in the form of a sensation of obstruction. Within two to four weeks a sharp diarrhoea with colic appeared. All the patients complained of an unusual degree of weakness; all were pale and lost weight rather rapidly.

A larval phase of hookworm disease is described which is characterized by loss of strength and weight, anaemia, irregular fever, a definitely high eosinophilia and leucocytosis, possibly diarrhoea, and a light intestinal worm burden, indicating that only a small percentage of larvae had been able to reach the intestines, the rest remaining as a wandering or arrested group in the tissues. There may be no worms at all in the intestine, no ova from which to make a diagnosis, and only the blood and the history of the case to suggest a larval invasion and a frustrated uncinariasis. No adequate remedy has as yet been found for this larval stage of the disease.

This is by no means a complete list of the diseases and public health problems studied by the International Health Division but those abstracted above are the most important from the Indian standpoint and we regret that lack of space precludes even the briefest mention of the many other important branches now financed by this remarkable Foundation.

A MALARIA SURVEY OF AJMER, 1933-34. BY S. D. AHUJA, M.B., B.S. (PUNJAB), L.R.C.P. (LOND.), M.R.C.S. (ENG.), D.P.H. (LOND.), D.T.M. (LPOOL), MALARIA OFFICER, MUNICIPAL COMMITTEE, AJMER

This is an account of an enormous output of sanitary work carried out, apparently by the author, single-handed.

Data were collected on the spleen and parasite indices of the children, the mosquito breeding places scheduled, larvæ collected monthly, and adult mosquitoes caught and dissected.

The breeding places were dealt with on approved principles and a chart shows corresponding good results to the fever death rate.

In conclusion we quote the author's opinion on legislation in advance of public opinion:—'It is a sound rule not to have a recourse to law until all other means have been exhausted. Co-operation and not coercion is required'.

ANNUAL REPORT OF THE EXECUTIVE HEALTH OFFICER OF THE CITY OF BOMBAY FOR THE YEAR 1933. BY J. S. NERURKER, B.Sc., L.M. & S., D.P.H., EXECUTIVE HEALTH OFFICER

THIS is a valuable report full of detailed information for which the reader is referred to the original.

The year began with a very severe epidemic of smallpox which lasted till the 3rd of June 1933. This epidemic is partly responsible for raising the death rate that was going down steadily in the last four successive years. The health conditions otherwise were very good. The number of live births registered during the year was more by 3,752 than the number of deaths that took place in the city. This excess of births over deaths was equivalent to 3.2 per 1,000 of population calculated on the census of 1931 and was recorded in succession for the third time. Before 1931 there had been no such excess since 1866, the year in which birth records were instituted.

The number of live births registered was 30,926 being 2,032 more than in 1932, 7,474 more than the average of the last ten years (1923—1932) and the highest on record since 1866. The birth rate calculated on the census population of 1931 was 266 births per 1,000.

The total number of deaths from all causes was 27,174 being 4,318 more than in 1932, 1,298 more than the average for the last five years (1928—1932) and 2,596 less than that of the preceding decennium (1923—1932). The death rate or the number of deaths in the year per 1,000 of the census population of 1931 was 23.4, as against 19.7 in 1932 and 23.8 the rate recorded for the decennium 1923—1932.

Plague was reported as the cause of 48 deaths during the year as against 37 in 1932 and 255 the average of the last ten years (1923—1932). Smallpox caused 2,659 deaths as against 313 in 1932 and 737 the average for the last decennium (1923—1932). Cholera was registered as the cause of 17 deaths being 10 more than in 1932 and 32 less than the average for the ten years (1923—1932). Influenza was prevalent in a mild form in the city during the year and caused 76 deaths as against 76 in the preceding year and 105 the average for the last decennium (1923—1932). The deaths from diseases of the respiratory system numbered 9,102 being 820 more than in 1932 and 1,859 less than the average of the last ten years (1923—1932). Tuberculosis accounted for 1,594 deaths as against 1,389 in 1932 and 1,553 the average for the preceding decennium (1923—1932). Seventy-one deaths were due to malaria, being 5 less than in 1932 and 267 less than the average of the last decennium (1923—1932). There were 1,192 deaths from ague and remittent fever as against 1,217 in 1932. The average number of deaths for the last ten years (1923—1932) from malaria was 338 and from ague and remittent fever 1,847.

The deaths among infants under one year of age numbered 8,320 against 6,298 in 1932 and 7,595 the average for the last ten years (1923—1932). The rate of infant deaths per 1,000 births registered was 269.

Compared with the decennial averages (1923—1932) the total number of deaths shows a decrease of 2,596,

the principal decreases in the mortality being 207 under plague, 267 under malarin, 655 under ague and remittent fever, 897 under diarrhoea, enteritis and dysentery and 1,859 under diseases of the respiratory system. There was also a similar decrease of 32 deaths under cholera, 37 under measles and 29 under influenza. On the other hand, there was an increase of 80 deaths under enteric fever, 1,922 under smallpox and 41 under tuberculosis.

Correspondence

GRANULOMA VENEREUM

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—Will you kindly publish the following as a contribution to the controversy regarding the venereal origin of granuloma venereum.

In the venereal department of the General Hospital, Madras, we have examined and treated 230 males and 138 females suffering from granuloma venereum during the past five years (1930 to 1934). These cases were drawn from all over the province including the Northern Circars. These 368 cases, in my opinion, constitute the largest number seen in a single clinic and hence we can lay claim to have some clinical experience of this distressing malady. The table shows the total number of patients seen in this clinic each year with the number and percentage of granuloma cases.

An examination of this table reveals, among other things, an absolute larger number of males than females suffering from the disease, but, when taken in relation to the total number of cases who attended the clinic, the females show a relative preponderance. This relative preponderance of female patients is much more striking in the first three years and becomes less marked in 1933 and 1934, though the total number of females who attended the department has shown a progressive increase from 1930 to 1934.

TABLE

Year	MALES			FEMALES		
	Total patients	Cases of granuloma venereum	Percentage	Total patients	Cases of granuloma venereum	Percentage
1930	5,663	53	0.9	942	58	6.2
1931	5,507	48	0.9	868	22	2.5
1932	5,637	57	1.0	1,105	31	2.8
1933	5,579	38	0.7	1,078	17	1.6
1934	5,489	34	0.6	1,219	10	0.8

It is a clinical fact that lymphogranulomatosis of the vulva, perineum, etc., has such a close similarity to the lesions of granuloma venereum in the same situation that the former can be differentiated only with Frei's intradermal diagnostic test. We have been using Frei's test systematically in the diagnosis of vulvar and anal ulceration only from 1933 onwards. Hence the marked relative preponderance of female patients in the years 1930 to 1932 is due to the fact that a large number suffering from lymphogranulomatous ulceration must have been included in the venereal-granuloma group. With more accurate diagnosis and by excluding other venereal conditions affecting the genitalia of women (besides

lymphogranuloma of the vulva we have seen a few cases of extensive syphilitic ulceration of the vulva, perineum and peri-anal region in women which are clinically indistinguishable from venereal granuloma, short of the serological reaction and therapeutic test), it will be seen that the difference in the sex incidence is not so striking as to warrant an opinion against the venereal hypothesis. Further, the analogy of other venereal cases attending a clinic showing a preponderance of males over females is not always true, as can be inferred from the table below showing the incidence of syphilis for four years (1930 to 1933) in our clinic in Madras.

SYPHILIS CASES, PERCENTAGES

		Males	Females
1930	..	28	31
1931	..	27	33
1932	..	31.5	39
1933	..	33	47

In over 95 per cent of our male patients with granuloma venereum, there was a definite history of sexual exposure and the development of a penile sore preceding, by a variable period, the onset of typical granuloma venereum. In many instances the original lesion had healed without any treatment or the patient had undergone an operation for circumcision for the non-healing of the sore. In some cases the penile lesions slowly became a spreading granuloma. We have seen three such primary lesions which disappeared under antimony treatment and broke down a few months after. Such an invariable history of sex contact and the development of a penile lesion cannot be a coincidence but must bear an aetiological significance. In the case of women, for obvious reasons, such a history is not obtained or obtainable.

As regards the incidence of granuloma as between married women and prostitutes, our statistics tell an absolutely different tale from that of Drs. Nair and Pandalai. There is a great preponderance of prostitutes over married women, with 63 per cent of the former against 29.6 per cent of the latter. In 7.4 per cent of the cases, the exact social status of the women could not be correctly ascertained. It should be remembered that the disease is more persistent, painful and disabling in women than in men. In the case of our married female patients suffering from the disease a history of the husband having suffered from venereal sores could be obtained in a majority of cases, but only in one case could we get the husband for examination. He gave a history of a penile sore a few months before the appearance of a typical granuloma in his newly-wed wife. The husband showed a small partly-healed granulomatous sore on the inner aspect of the prepuce. Tests for other venereal diseases were negative.

The invariable association of secondary extra-genital lesions, lips, mouth, palate, etc., with either active genital lesions or scars of past disease is a strong point in favour of the venereal origin of the disease. We have examined 15 cases of extra-genital granulomas and in 13 of them they were associated with and secondary to genital lesions. We had two cases of peri-anal granuloma without genital lesions in boys of 14 and 16 who were professional passive agents in sodomy and in whom the tests for other venereal diseases were negative. This is certainly a venereal origin of the disease. The analogy of filariasis cannot be used as an argument to show that a genital situation is not necessarily venereal. Filariasis of extra-genital regions of the body is as, or even more, frequently seen as that of the external genitals. The comparative rarity of purely primary extra-genital granulomas and the preponderating frequency of genital lesions should certainly be a convincing argument for the majority point of view. The fact that a few

cases of venereal granulomas were observed in children or sexually inactive persons proves nothing except that extra-genital infection is possible, as it is in the case of syphilis.

The question of trauma as a factor in this condition needs proper study. In our series the trauma took the form of surgical operations for circumcision, buboes, etc. But in all the cases there was a pre-existing venereal lesion for which the operation was performed. In no case did an operation on a normal prepuce result in the development of a granuloma, so that trauma *per se* does not seem an important factor except that it probably helped to spread or activate the disease, and has the same aetiological value as trauma in syphilis.

It is well known that the disease has a predilection for stratified epithelium which accounts for the absence of involvement of the urethra, bladder and internal genitalia. That the vagina proper and the vaginal aspect of the cervix, though lined by stratified epithelium, are not affected in this disease, may require further investigation or may signify some innate resistance. The adult vagina is resistant to gonococcal infection though the cervical canal may be teeming with gonococci and the fornices may be bathed in purulent highly infectious secretions.

It is our opinion, though largely speculative and impressionistic, that there is a primary lesion of venereal granuloma. The primary lesion is more often recognizable in the male than the female as it is more obvious to the former and brings him to the doctor. The typical spreading, scarring granuloma seems a tertiary manifestation of the infection and does not appear to be contagious to others. Clinical manifestations of granuloma are more devastating and disabling in women than in men. It is quite likely that a larger number of men escape with the primary lesion. The greater moisture, dirt and trauma, to which the female genitalia is liable, may also account for the alleged greater frequency of the condition. If one takes into consideration genital lesions of other venereal diseases, *e.g.*, syphilis and lymphogranulomatosis, in the two sexes, one finds a contrast in the situation, extent and magnitude of the lesions. The multiple, giant, hypertrophied, condylomatous syphilides which are often found in the genitalia of women are not seen in the corresponding regions of the male genitals with such frequency. The chronic, indolent, elephantoid granulomatous ulceration of the vulva, which is frequently observed as part of the syndrome of lymphogranulomatosis in women, has no counterpart in the disease in men. Such being the case we should not be surprised if a similar contrast is observed in the case of granuloma venereum.

To sum up, a history of sexual exposure, the antecedent appearance of a primary penile lesion in the vast majority of males suffering from granuloma, the preponderating incidence in the genital region, and the few cases of purely extra-genital lesions in whom unnatural sexual practices could be proved do warrant the assumption of a venereal origin of the disease if they warrant anything at all. In the discussion of a disease from a clinical and scientific point of view, moral and social considerations are beside the point and it is a pity that the term 'venereal' has come to be associated with them through centuries of usage. As medical men, in discussing venereal disease we may recall to our mind what Stokes says in writing about the epidemiology of syphilis that 'it is not a divine moral purpose nor a satanic punitive ingenuity that connects syphilis with genital activities, but a mere biological accident, no more significant in the last analysis than the fact that potatoes grow in a sandy loam'.—Yours, etc.,

R. V. RAJAM, M.B., M.S. (Mad.), M.R.C.P. (E.),
Venereal Specialist.

GENERAL HOSPITAL, MADRAS,
19th January, 1935.

Service Notes

APPOINTMENTS AND TRANSFERS

LIEUTENANT-COLONEL W. C. SPACKMAN, on return from leave, on the 17th January, 1935, is appointed to be Professor of Midwifery and Gynaecology, Grant Medical College, and Superintendent, Bai Motlibai and Petit Hospitals, Bombay, *vice* Captain H. S. Waters, transferred.

The services of Major C. M. Nicol are placed temporarily at the disposal of the Government of the Punjab for employment as Assistant Director of Public Health, with effect from the date on which he assumes charge of his duties.

Major A. Y. Dabholkar, M.C., is confirmed in the appointment of Director of Public Health for the Government of Bombay.

Captain H. S. Waters, on relief, to be on general duty at the St. George's Hospital, Bombay, pending further orders.

The services of Captain P. L. O'Neill are placed temporarily at the disposal of the Government of Bihar and Orissa, with effect from the 10th November, 1934.

The services of Captain G. R. M. Apsey and Captain W. McAdam are placed temporarily at the disposal of the Government of Burma, with effect from the 7th November and the 12th November, 1934, respectively.

The services of Captain Sangham Lal and Captain J. S. McMillan are placed temporarily at the disposal of the Government of Madras, with effect from the 14th November and 15th November, 1934, respectively.

The services of Captain R. A. Wesson are placed temporarily at the disposal of the Government of the United Provinces, with effect from the 16th November, 1934.

LEAVE

Lieutenant-Colonel W. J. Simpson, an Agency Surgeon, is granted leave, preparatory to retirement, for 6 months and 14 days, with effect from the afternoon of the 12th November, 1934.

Previous notification is hereby cancelled.

Major J. S. Galvin, Civil Surgeon, Sholapur, has been granted by the High Commissioner for India extension of leave for one month and 26 days in continuation of the leave granted to him in the previous notification.

Major A. Y. Dabholkar, M.C., Director of Public Health for the Government of Bombay, is granted leave for eight months out of India, from 1st April, 1935, or subsequent date of relief.

Captain G. B. W. Fisher, Civil Surgeon, Rajshahi, is granted leave for three months and in continuation furlough in or out of India for one month and five days, with effect from the 7th November, 1934.

This cancels previous notification.

PROMOTIONS

To be Lieutenant-Colonels

- R. H. Malone. Dated 6th November, 1934.
- V. N. Agate. Dated 11th November, 1934.
- J. P. Canteenwalla. Dated 15th November, 1934.
- L. S. Modi. Dated 15th November, 1934.
- H. A. Khin. Dated 19th November, 1934.
- M. S. Joshi. Dated 23rd November, 1934.
- K. B. Gharucha. Dated 26th November, 1934.
- H. S. Anand. Dated 26th November, 1934.
- B. H. Kamakaka, M.C. Dated 29th November, 1934.

To be Captain

deLisle Carey, 24th October, 1934, with seniority Lieutenant 15th March, 1926, and as Captain 15th March, 1929.

RETIREMENT

Lieutenant-Colonel J. Morison, C.I.E., retires, 6th November, 1934.

Notes

'TABLOID' FINE-GRAIN DEVELOPER

A DEVELOPER specially intended for the production of fine-grain negatives has been introduced by Burroughs Wellcome and Company. It is known as 'Tabloid' Fine-Grain Developer and may be used for miniature or other films or plates which it is desired to enlarge to a considerable degree.

This is a developer possessing distinct and original features of its own. Its use does not demand increased exposure nor increased development and it gives negatives free from fault or chemical blemish even when used with the fastest of fine-grain films. It is prepared from ingredients of exceptional purity, a point of great importance in miniature negative work.

Dissolved in plain water, it is a most satisfactory fine-grain developer for negatives designed to be enlarged up to about 10 diameters (V. P. K. to 20 × 15 approx.), and has this further advantage, that if a 20 per cent solution of anhydrous sodium sulphite is used, instead of part of the water, the grain is still finer and permits of much greater degrees of enlargement.

A time-table is given of correct times for developing different films at different temperatures. Factors for factorial development are also given on the cartons so that development to the correct degree of contrast is rendered delightfully simple.

'Tabloid' Fine-Grain Developer is issued in cartons each containing materials sufficient for preparing 30 ounces of normal strength developer, or 60 ounces of tank developer.

STAINING SLABS

By F. R. W. K. ALLEN, M.A., M.B. (Dub.)

MAJOR, I.M.S.

I WOULD request you to draw the attention of all medical men who have a large number of blood films to examine for malarial parasites to Butler's staining slabs in case some do not know of them.

By the use of one slab, twelve thick blood films can be beautifully and simultaneously stained.

These slabs consist of a trough $\frac{1}{4}$ th inch deep by 1 inch wide cut in a glass plate $\frac{1}{4}$ th inch thick by 2 inches wide by 12 inches long. They were invented by one of the Directors of Medical Services in East Africa.

The blood films are inverted and some form of Romanowsky stain run into the trough. Here we use Leishman's alcoholic solution, diluted equal parts with water, but in East Africa Giemsa's stain is the most popular. It is not necessary to dehaemoglobinize the films before staining. After staining for 7 to 10 minutes distilled water is simply run into the trough for sufficient time to wash away all traces of the stain from the glass. The twelve slides are then dried and examined.

Our slabs were obtained from Messrs. Allen & Hanburys, Limited, London.

OVARIAL AND LUTEAL

THE glandular preparation, ovarian, has been introduced by the National Opothérapie Institute, Pisa, and is said to contain the active principles of corpora lutea and the hormones of the ovaries. It is prepared in two forms, one for oral administration and one for the now-popular intramuscular injection. Whilst one must deplore irrational polyglandular therapy, it has to be admitted that the intelligent use of glandular extracts have proved very valuable in the treatment of many conditions which hitherto proved very resistant to any form of treatment. It is claimed for this particular extract that it is of value in a large variety of menstrual disorders at all ages, at the menopause, to obviate the nervous and psychic conditions that often occur at this time, and in general neurasthenia and in the psychoses of pelvic origin.

Luteal, another preparation from the same institute, contains only extract of corpus luteum; this is mainly recommended for use at puberty and during pregnancy. It is administered by intramuscular injection.

A NEW CLAMP FOR STOMACH OR INTESTINE

By T. H. SOMERVELL, M.A., F.R.C.S.

ARTER over twelve years of continual gastric surgery in South India, I have at last managed to get the perfect stomach clamp.

All types of the ordinary shape, whether with thick or thin blades, have a tendency to damage the stomach (or intestine) in some places, while insufficiently gripping in others; and Wells overcame this difficulty by making a hinge in the middle of one of the blades, the blade itself being attached to the hinge by springs. But the Wells' clamp is difficult to clean, and has to

egg and cheese dishes, fish, meat and savoury dishes. For invalids and for vegetarians and for those for whom a restricted diet is prescribed, it is particularly useful.

For infants marmite may be included in the ordinary feeds, and for older children it may be spread on rusks or served as broth. With children, as with adults, spread on bread and butter, or on buttered toast it is very popular.

Physicians who prescribe raw liver in the treatment of pernicious anæmia often advise that marmite should be mixed with it, as this serves the double purpose of disguising to a certain extent the disagreeable flavour of the liver while enhancing its therapeutic effect. Patients report that this mixture is infinitely preferable to the raw liver.

It is well known that the administration of sufficient active material is of the utmost importance in the

be made, in part at least, of ordinary steel, the plating of which wears away.

I have, therefore, designed a simpler clamp on the same principle, but embodying the spring in the arm between the hinge and the pivoted blade.

Messrs. Down Bros. have made two of these clamps for me, and I have tested them thoroughly during 1934 in a large number of operations on the stomach, as well as on the intestines. I can bear witness to the excellence of the clamps both in their performance and in their makers' workmanship.

The clamp holds the gut firmly, yet gently and with uniform pressure. It can be made of stainless steel throughout and is easy to clean. The pivoted blade should be enclosed in rubber tubing, and if that is done this clamp causes the minimum of damage to the mucosa of stomach or intestine. It is 'easier to be gentle' with this clamp than with Wells', Kocher's, Beck's, or any other type of clamp that I have seen.

The bent handles enable two clamps to be used side by side without undue pulling of the gut, besides allowing them to be removed independently with ease.

ON PRESCRIBING MARMITE

THE value of marmite in anæmias and certain other deficiency diseases is now definitely established. The most suitable method of administering it will vary according to circumstances. The following are some methods suggested by the manufacturers.

METHODS OF ADMINISTERING MARMITE

It may be just served as clear soup, prepared by stirring a small teaspoonful of the extract into a cup of hot water. This may be varied by the addition of a well-beaten egg, or, when allowed, one or two teaspoonfuls of sherry. Marmite made with hot milk instead of water provides a particularly nourishing and pleasant beverage, or of course it may be added to soups of all descriptions, thick and clear.

Feed marmite made in the same manner as other iced drinks is often appreciated, especially by invalids, during warm weather.

Made into a paste with about three times the quantity of butter, it forms an appetizing sandwich filling. This mixture may be spread on bread, toast, rusks or biscuits.

As a culinary adjunct, it may be incorporated in a variety of other dishes—sauces, stews, pies, gravies,

treatment of pernicious anæmia, and that recorded failures with liver therapy have been shown to be due usually to inadequate dosage, to inactive material or to septic foci.

The daily dose advised is half to four drachms according to the circumstance.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

DRUG ADDICTION IN INDIA AND ITS TREATMENT

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

Professor of Pharmacology

(Drug Addiction Inquiry, Indian Research Fund Association Series No 21)

Introduction

ALTHOUGH in India drug addiction has existed on a more extensive scale than in any other country in the world with the exception perhaps of China little is known regarding the problem. Two commissions were appointed to go into the matter at the end of the last century; a Royal Commission was appointed in 1893 to enquire into the prevalence of the opium habit, and a commission to go into the question of hemp drugs was appointed by the Government of India in 1895. Both these commissions collected important information regarding the prevalence and effects of these drug habits in a general way, but unfortunately the medical and scientific aspects of these addictions were not inquired into fully at that time. Nearly forty years have elapsed since these commissions did their work. Considerable changes have occurred and new drug habits have come into being, yet a perusal of the literature shows that very little work has been done on this important subject. The information available even with regard to the present-day incidence of the drug addictions is meagre. The temperance and anti-opium societies have published some data, but these are biased, and often inaccurate and misleading. Even such an important subject as infantile administration of opium, which is still so prevalent, is doing an enormous amount of harm, and is probably a cause of the high infantile mortality in some communities, has not been systematically investigated. Opium eating is very prevalent in many parts and opium smoking is indulged in freely in Assam and other areas. The hemp drugs are used to an enormous extent. No systematic work has been done to determine the ill-effects produced by these drug habits. Some years ago the Indian Research Fund Association gave the writer a small grant to investigate the drug addiction in this country and some interesting data have been collected. A list of papers published in this connection is given at the end of this memorandum. It is obvious that the inquiry has only touched the fringes of this vast problem. The wide experience the writer has of the problem as it exists in different parts of India leads him to the conclusion that the subject is of vital importance—from the social,

economic and health points of view. In this paper it is proposed to give a brief review of the work done by this inquiry.

The problem of drug addiction in India presents many features which are widely different from those met with in western countries and about which a great deal of misapprehension exists in Europe and America. The habitual use of drugs of a stimulative and restorative character was prevalent in India probably before they were used in any of the other countries of the modern world. The juice of the 'soma plant' was a favourite drink of the Aryan settlers and was regularly taken by them many centuries before the Christian era. What exactly the 'soma plant' was, is not known, though a number of plants, such as *Cannabis sativa*, *Ephedra vulgaris*, *Asclepias acida*, have been implicated. During the Hindu period, i.e., up to the 8th or 9th century A.D., alcoholic beverages were used by the people as well as the preparations made from hemp drugs. These produced not only a sedative effect, but also brought about euphoria in the form of pleasant dreams, forgetfulness and, it would also appear from the writings of that period, voluptuous satisfaction. Opium and poppy were introduced on the west coast about the 9th century A.D. by the advent of the Mohammedan traders, and opiates soon came into use. A study of records shows that during the period of the Moghul Empire, alcoholic beverages, opiates and hemp drugs were freely used. A decoction made from poppy capsules known as *koknar* was extensively used all over India, and is used to the present day in parts of the Punjab. A beverage containing wine, opium, Indian hemp and poppy capsules, known as *chaharbargha* (four-leaved), was drunk by the well-to-do classes in the time of Akbar (1556 to 1605) and later. Opium on account of its stronger effects appears to have taken a great hold of the people and poppy was extensively cultivated all over the country during this period and was indulged in by all classes.

OPIMUM

Opium eating and smoking.—The author's work in the field has shown that most of the raw opium sold in the country is used for addiction purposes in one form or another. It is generally consumed in the form of a pill or solution in water. Opium smoking although not common is still practised in the lower strata of society in many parts of the country. It is common in Assam and in certain parts of the Central Provinces and Berar. The proportion of opium smokers to opium eaters in Assam has been variously estimated from one-third to half of the total addicts, but our recent enquiries show that the number has now come down to a quarter. The Government of India and all the provincial governments have adopted the policy of checking opium smoking by

diminishing the facilities for the practice of the habit through legislation. These measures have succeeded to a great extent and as a result of this the habit has greatly declined.

Although opium is habitually used by large sections of the population at the present time, the indulgence is not so widely prevalent as might be imagined from some of the recent publications on the subject. The Government of India have strictly adhered to their promise to the League of Nations and have progressively reduced both the production and consumption of opium. We have shown that, although if the country is taken as a whole the consumption of opium is low, in certain parts it is very high. For example, in Bengal presidency taken as a whole, the consumption per 10,000 of population is 8 seers per annum instead of 6 seers required for the medical and scientific needs; in the town of Calcutta it is 58 seers, Hooghly district 21 seers, Howrah 16 seers and 24-Parganas 15 seers. In the Madras presidency taken as a whole it is 8 seers, but for East Godavari and West Godavari it is 37 and 22 seers respectively. For the Punjab as a whole it is 12 seers, but for Ferozepore district 33 seers, Lahore 34 seers, Ludhiana 25 seers, Amritsar 30 seers. For the whole of Bombay presidency it is 10.05 seers, but is considerably higher in the towns of Bombay and Ahmedabad and in Broach district. In the whole of the Central Provinces and Berar it is 9.0 seers, but in Amraoti it is 40 seers, Akola 50 seers and in Balaghat 30 seers. For the United Provinces as a whole it is 4 seers but the incidence is high in a few districts, *e.g.*, Cawnpore, Benares and Lucknow, where the consumption rate is 19, 21 and 17 seers respectively. In Assam as a whole it is 19 seers, but in Lakhimpore it is 70, Sibsagar 45, Nowgong 27, Darrang 22 and Kamrup 8.9 seers. The highest consumption rate recorded in India is in the Sadiya frontier tract, being 94 seers. The high figures are due to smoking of the drug, which necessitates a much higher consumption per head.

On the other hand, there are extensive areas in all provinces where consumption is very low, *i.e.*, 1 to 5 seers per 10,000 of population per annum. Such areas are now on the increase. In Assam, Goalpara and Sylhet are the examples. In the Bombay presidency (Kanara and Bijapore) and in the United Provinces many of the districts can be grouped under this head. In the Punjab there are 20 out of the 29 districts where the consumption of opium is below the standard laid down by the League of Nations as being necessary for purely medical and scientific needs of the population, *i.e.*, 6 seers or 12 pounds per 10,000 of population per annum.

It will thus be seen that the habit is not widely disseminated among the population, its incidence among various classes is very irregular. The areas with a high consumption rate are being investigated with a view to determining the causes which have led to it, and steps are being taken to put down excessive use of the drug. A perusal of the following table will show that the consumption of opium in India has fallen considerably during the last 20 years:—

Year	Consumption of opium in seers* in British India (excluding Indian States)	
1912-13	..	506,664
1930-31	..	241,211
1931-32	..	213,000

* 1 seer is approximately equal to 2 pounds.

If 10 grains is taken as the average daily dose, then there are roughly 1 to 1½ million persons in India who habitually take this drug.

The average dose taken in the writer's recent series of over a thousand cases was roughly 10 grains daily

per addict as compared with 20 grains worked out by the Opium Commission of 1895.

Addiction to opiates in this country, although it is still very extensive, does not appear to exist in such intense and pernicious form as it does in the west with morphine and other alkaloids of opium. It may be stated here that in the old days, when opium was cheap, addicts were undoubtedly met who took 180 to 500 grains of the drug daily. The writer in recent years has met with only a few individuals who took more than 50 grains daily; many of the old addicts, however, take more than 15 grains daily. The chief reason for smaller dosage is that the price of opium has risen enormously. Whereas during the pre-British period, in the Punjab, opium used to sell at 2 to 3 annas (2 or 3 pence) per 'tola' (180 grains or 12 gm.), in 1901-02 it cost 8 annas for the same amount and in 1929-30 Re. 1-12-0 (half a crown).

Administration of opium to infants.—Habitual administration of opium to infants at certain periods of their lives has been prevalent in India for many centuries. The habit appears to have been started because of the drug's power of allaying diarrhoea and vomiting, relieving cough and pain, and producing sleep. The custom, although it is still met with in almost every part of India, has greatly declined during the last two or three decades. The drug, however, is still extensively employed in the Central Provinces and Berar and in the industrial areas in all parts of India.

In Berar it is stated that 75 per cent of the infants are doped with opium and that 25 per cent (*i.e.*, 6,198.5 lbs.) of the total opium consumed goes to infants. The consumption is still higher in the cotton-growing areas where children account for 40 per cent of the total consumption. The main reason for administering opium is economic, the drug being given to keep the children quiet so as to allow the mother to carry out her work, whether in the factory or the field, unhampered. The practice is begun during the first few weeks of the infant's life, the earliest time to commence being 3 weeks and the latest period 3 months. The drug is usually discontinued when the child attains the age of 2 or 3 years, that is when it begins to play about and can live on ordinary food. The dose varies from one-eighth of a grain to three grains daily. The drug affects the child's health adversely and hinders growth. The children receiving opium have an emaciated, unhealthy and toxic appearance. They are more liable to catch infections and to attacks of epidemic diseases and the mortality rate among them is comparatively high. Although deaths from overdosage are not frequent, they do occur. Non-fatal overdosage is not uncommon.

Addiction to Post (unlanced capsules of Papaver somniferum).—The poppy capsules are known to have been used for their saporific properties by the ancient Egyptians, Greeks and Romans. For many centuries they have been used in the Chinese, Hindu and Mohammedan medicines as a sedative in inflammatory diseases of the alimentary and respiratory tract. During the 16th, 17th and 18th centuries when the Moghuls were in power in India, the capsules were extensively used to prepare a beverage which had soothing and euphoric effects and which was almost universally indulged in. The habitual use of poppy capsules for euphoric purposes has considerably

decreased during the last three decades but the addiction is still prevalent in certain districts of the Punjab, and in many parts of Rajputana. The present writer after a study of over 500 addicts has come to the conclusion that habitual use of poppy heads produces physical, mental and moral degeneration in the habitué; as compared with the opium habit its effects on the individual are much more pronounced.

Addiction to opium alkaloids.—Habitual use of morphine has considerably increased in India during recent years, the increase at present being confined to northern India. There appears to be grave danger of rapid extension of this habit to other parts if steps are not taken to check it. Morphine addiction among Indians is usually met with in young persons between the ages of 20 and 25 years. The habit is not started for the sedative and analgesic effects of the drug as in western countries, but for its euphoric effects and because of its supposed aphrodisiac properties. Formerly the alkaloid was taken almost exclusively by the mouth, but recently the injection method is coming into use. By this latter method, the effects produced by the drug on Indians are very similar to those produced by cocaine. The habit produces a state of chronic toxæmia and detrimentally affects all tissues of the body, particularly the nervous tissues. In morphine habitués physical, mental and moral deterioration sets in much more rapidly than in opium addicts.

Two kinds of poisons are concerned in producing the toxæmic state: (1) the exogenous poison, *i.e.*, the drug itself which is rapidly absorbed after injection and circulates in the blood, and (2) the endogenous toxins which are formed by the action of the alkaloid on the general metabolic processes of the body, biochemical changes being thereby set up. Both these factors combined interfere with the normal functions of the organs giving rise to debility and malnutrition. General toxæmia and improper assimilation of food products lead to wasting, sallow colour and anæmia, and finally a cachetic condition may supervene. Addiction to other alkaloids of opium, *e.g.*, codeine and heroine, is very rare in this country.

HEMP

Indian hemp grows wild in the montane and submontane tracts over the whole of the north-eastern and north-western parts of India and three of its preparations, *i.e.*, *bhang* (dried leaves), *charas* (resinous exudate) and *ganja* (flowering tops) were in the past largely used by the poorer classes, on account of their very low cost. Even to the present day hemp drugs are the narcotics most extensively employed by the poorer classes throughout the country. Extensive work in the field has enabled the writer to estimate approximately the prevalence of hemp drugs addiction in India and, taking the country as a whole, the incidence of addiction in British India ranges between 0.5 to 1.0 per thousand of the population. In south India where the spontaneous growth of *Cannabis sativa* does not occur, hemp was and is still cultivated for use as a drug of addiction.

The following table gives the total quantities of hemp drugs supplied through licit sources used for habitual consumption in India :—

1912-13	996,783 seers
1930-31	547,630 "
1931-32	511,307 "

Besides this there is little doubt that large quantities reach the people through illicit sources also.

From a close study of 1,500 cases, the average dose worked out in the case of *charas* and *ganja* is 5 to 10 grains daily and of *bhang* a little more than double this. There are approximately 1 to 2 million persons in India who habitually consume hemp in one form or another. The consumption of hemp drugs is highest in the United Provinces and then follow Sindh, Delhi, the Punjab and North-West Frontier Provinces.

The physical and mental effects produced by these drug habits appear not to be so marked as opium, but they undoubtedly lead to mental and moral degeneration. When under the effect of these drugs, the addicts appear to lose all idea of correlation of time and space. They forget their environment and do not know what they are doing. *Ganja* and *charas* are much more potent in this respect than *bhang* and their excessive consumption, especially of the latter, gives rise to insanity and leads to crime. This was one of the points discussed by the Hemp Drugs Commission, but no definite conclusions could be arrived at. Some work has been done by the author in this connection in the Ranchi Mental Hospital. Out of 1,600 patients examined in this hospital as many as 600 (35.5 per cent) gave a history of drug addiction; in more than half of the latter, the history of hemp drugs (*charas* and *ganja*) addiction, and in a third the history of alcohol could be distinctly traced. Out of 600 cases discharged from the hospital as cured, in 213 the cause of insanity was drug addiction. Out of 350 criminal insane patients, 114 or 38 per cent gave a history of addiction to hemp drugs. These figures appear to show a distinct relationship between drug addiction, insanity and crime, but to come to a definite conclusion more work is necessary.

Alcohol.—The use of distilled alcoholic liquors has extended during the early part of this century but has decreased lately. In the old days distilled liquors were used to a very limited extent; wines were largely used. The aboriginal races of India made a beverage by fermenting rice—*pachwai*—and by fermenting palm juice—*tari*. Both these are extensively used in many parts of India to the present day. The fluid that is habitually drunk by the Nagas of the Assam hills (Manipur State) is a weak country beer called *zu*. The present writer has shown that the alcoholic content of the majority of the crude beers used in India is low and their nutritive value is very high. Some of these beers are rich in vitamin content which is often poor in the general dietary of the people who drink them. The areas where such beers are consumed are remarkably free from deficiency diseases. Distilled country liquors and foreign liquors are used by the richer classes to a comparatively lesser extent.

The drinking of youth and the social drinking in the endeavour to mitigate the wear and tear of life and to get relief from its annoying factors, as it exists in the west, is not commonly found among Indians. Extensive habitual use of alcohol is uncommon and

the harmful effects produced by it are rarely encountered. The problem of alcoholism has not up to the present time assumed a serious aspect in this country. It may however be pointed out that the use of distilled country liquors is rapidly increasing in certain areas and in many parts of India drunkenness is being more frequently encountered among the masses. This is due to the fact that while restrictions are being imposed on the sale of opium and hemp drugs and their price has risen owing to the increase of excise duty, in spite of the high excise duty a bottle of distilled liquor can still be purchased for a few annas. Country liquors in many parts are taking the place of opium and hemp drugs.

Cocaine.—The present writer has shown that cocaine came into use quite accidentally about 50 years ago. In spite of all the restrictions imposed on the import, possession and sale of the drug, the habit has spread from Calcutta to large towns along the two main railway routes through the Central Provinces into the Punjab and the North-West Frontier Province. From Bombay it spread to some of the large towns in that presidency. Cocaine is not manufactured in India but is smuggled into the country in large quantities. For some time past the Far Eastern has driven the European and American manufactured product out of the market. The drug is illicitly brought by crews of ships running between Calcutta and the Far East and is heavily adulterated before it is sold. Cocaine is usually taken in the form of an injection or as a snuff in western countries, but at present practically the only method of taking the drug in India is by the mouth. It is commonly consumed by putting it in *pan* or *betel* leaf, and for that reason addiction to this alkaloid is prevalent among the *betel*-leaf-chewing population of north-west India, Bengal, Bihar, the United Provinces and the Punjab. The habit not only exists among the well-to-do people but a large number of the artisan class in large towns are also addicted to it.

It has been calculated by competent authorities that over 200,000 ounces of cocaine were smuggled into India in 1929 and that the consumers paid between Rs. 270 lakhs and Rs. 648 lakhs to the retailers for their doses of the drug. The symptoms and effects produced by it were studied in 200 cases; the cocaine habit is one of the most pernicious of the drug habits and the serious toxic effects produced by it on the Indian addicts have been shown by the present writer.

New drug habits.—During the last few years chloral hydrate as a drug of addiction has also made its appearance in northern India. It has come into use since the price of spirituous drinks has gone up considerably on account of the increased excise duty. Most of those that drink alcohol habitually in India do not take it merely to obtain mild excitement or sedative effects, as is usually the case in the west, but to obtain intoxicating effects. Owing to increase in the price of liquor they cannot afford to buy sufficient quantities for this purpose and the ingenious idea of potentiating the effects by adding small quantities of chloral hydrate

(0.5 to 1.0 gm.) has occurred to them. The drug is also sometimes mixed with tea and is habitually consumed by some people. The chloral habit has thus sprung up, though fortunately a very limited area is affected at present. The drug is powerful and toxic, and several fatalities have been reported from accidental overdoses. Chloral hydrate is a cheap product selling at about Re. 1-12-0 (half a crown) per pound, and as there are no restrictions to its sale at the present time it can be bought by anyone in any quantity from any chemist's shop. Half to 1 gm. or a little more added to an alcoholic drink produces symptoms of intoxication followed by sleep. The habit is harmful and dangerous. It is much more liable to produce pathological changes in the organs and immediately fatal results than any other drug of addiction in this country. The mental, moral and physical effects produced by this addiction are more pronounced than in any other drug habit. The drug is cheap and is easily procurable as there is no control over its sale. These factors are largely responsible for the spread of its use among the population in certain localities. There is a danger of the use of chloral hydrate for adulteration of alcoholic beverages (toddy, rice-beer, etc.) being extended and of the further spread of the chloral habit.

Barbituric acid derivatives.—During recent years a large number of the barbituric acid compounds have been introduced into therapeutics, including barbitone (veronal), sodium barbitone (medinal), luminal, dial, allonal, veramon, neobutal, amytal, evipan, pyramidon, etc. Circulars from manufacturing firms regarding the safe and sure action of these drugs have been freely distributed which influence not only the medical practitioners but the lay public also. Wilcox and Purves-Stewart have described a series of cases of addiction to barbitol and allied drugs, and the Drug Addiction Inquiry has been alive to the possibility of the formation of such habits in India. A number of fatalities resulting from indiscriminate therapeutic use and self-medication with these drugs have occurred and a few cases of addiction have also been observed among the educated classes in India. The fact that, besides the toxic effects produced by massive doses, the barbiturates also produce dangerous cumulative effects and a tendency to habit formation has not been sufficiently appreciated by the medical practitioners in this country. A warning is therefore necessary.

The drugs of this group have effective sedative and hypnotic properties, and, as they are analgesics also, they are largely used by the medical profession. In Great Britain all the barbituric acid derivatives are placed in Part II of the Poisons Schedule, 1918, i.e., they cannot be dispensed without the prescription of a qualified medical man. In India, however, they are not classed as poisons and are therefore not included in any of the schedules of the Poisons Act of 1919 (amended in 1931). These drugs can thus be bought

by any one and their use is increasing. The need for bringing the sale of barbituric acid derivatives as well as hypnotics like chloral hydrate, paraldehyde, sulphonal, trional, tetronal, etc., under control is therefore very urgent.

Briefly then the principal habit-forming drugs used in India are :—

1. Opium is still extensively used both by adults and infants. *Post* or *koknar* (unlanced capsules of *Papaver somniferum*) were largely used at one time, but owing to restrictions in the cultivation of the poppy their use is now limited to a small area in northern India. The use of morphine, though uncommon, is gradually increasing. It has been estimated that in British India alone out of a population of twenty-seven millions at least 1 to 1½ million persons take opiates habitually in spite of all the efforts that are being made to stop their use. In the Indian States especially in Rajputana the incidence is much higher.

2. Hemp drugs. *Bhang* (dried leaves), *charas* (oleo-resinous exudation) and *ganja* (dried flowering tops coated with resin) are extensively used all over the country in the lower strata of society on account of their very low cost. At a very moderate estimate at least 1 to 2 million of the population of India take hemp drugs habitually.

3. Alcohol. *Pachwai* (fermented rice) and *tari* (fermented palm juice) are largely used by the poorer classes. Distilled country spirit and imported liquors are used by the richer classes.

4. Cocaine was introduced 50 years ago; its use is spreading in northern India.

5. Chloral hydrate has been introduced during the last 10 years. Barbituric acid derivatives are being tried, the use of these drugs at present is limited; but there is danger of their extension for adulteration of alcoholic beverages.

Etiological factors.—It will be observed from the foregoing that the first three groups of drugs, which are commonly used in India, are mostly raw and crude products. In many cases they have to be prepared by the addict himself before use, which in itself limits their excessive consumption. Further by using crude products the addicts absorb comparatively smaller quantities of the active principles which are responsible for producing the toxic effects. In western countries almost all the drugs used for addiction purposes are highly purified products such as morphine, heroine and cocaine. Moreover many of these drugs in the west are taken in the form of injections. This method brings about the action more quickly and more intensely. At the same time the action is not so lasting as when the drug is taken by the mouth. All these factors lead to a greater desire or craving on the part of the addict for more frequent repetition of the dose and the habit is liable to be carried to excess and the addict to become a danger not only to himself

but to society. In India most of the common drugs of addiction are taken by the mouth and being crude products never produce such intense effects as are observed in western countries. A large number of addicts from the lower strata of society are so poor that they have not the means to carry the indulgence of even the crude and cheap drugs to excess; the upper classes are temperamentally more moderate. Besides, India is pre-eminently an agricultural country, which makes it possible for the majority of its inhabitants to lead a comparatively free and easy existence. The strain and stress of life which drive people to the habitual use of sedative drugs is not so great as in the west.

In spite of all these factors the problem of drug addiction is of very great importance from its extensiveness. The magnitude of the problem can be judged by the fact that, whereas in most of the countries in Europe and America the addiction rate of the population is from 0.1 to 0.2 per cent or even less, in many provinces of India the rate is 1 to 3 per cent or even more. These drug habits are responsible not only for much economic loss but they also lead to physical and mental deterioration and are of very great importance from the health point of view.

Another noteworthy feature of drug addiction in India, especially insofar as opium and hemp drugs are concerned, is the religious and social aspects of the problem. Indulgence in opium, on account of age-long usage and custom, is sometimes compulsory on such occasions as marriages, deaths and social gatherings among certain classes. Hemp drugs are considered to be the food of the gods and are offered in temples on religious festivals and ceremonial occasions. Some religious sects take these drugs under the belief that they help the individual indulging in them to free his mind from worldly attractions and in this way to concentrate on the deity. This is the reason why in places of religious worship, like Benares, Mathura and Puri, there is an enormous consumption of these drugs. Such use of these drugs is, however, rapidly decreasing.

The medical and semi-medical uses of opium and hemp drugs is another important factor. In a vast country like India, where the facilities of medical relief are poor, the majority of the population do not get the benefit of western medical science. The sedative drugs such as opium and hemp preparations are largely used as household remedies and habits are often formed from such use. The doping of infants with opium can partly be attributed to this. It is still firmly believed by the ignorant masses that opium is a wonderful tonic to the child, it stimulates his growth and prevents the child getting sick. The writer has discussed fully elsewhere the medical and semi-medical uses of opium and the large variety of conditions for which it is used as a household remedy.

Almost all the diseases for the relief of which opium and hemp drugs are used are of minor character. Often the drugs are taken to dry secretions from the conjunctiva and the respiratory tract. Many people suffer from toxæmias of focal sepsis, which causes pains of the rheumatic and neuralgic type, mental depression, irritability and hypersensitiveness of the nervous system; these drugs in small doses give them relief and they form the drug habit.

Opium is believed to stimulate physical energy. Those who have to do with coolies in the tea gardens and with labourers in rice and wheat fields in India realize the value of this drug to those who have been exposed to cold and chill. The writer found that the use of opium increased during the harvest season in many districts in the Punjab by 50 per cent.

TREATMENT

The medical profession in this country is very ill-informed on the subject of drug habits and their treatment. During the course of his investigations in different parts of the country, the writer had not come across many medical men who had any considerable knowledge regarding the treatment of drug addictions or of the phenomena which accompany abstinence. The general impression appears to be 'once a drug addict always a drug addict; he is incurable and that is the end of him'. Ordinary hospitals generally refuse to admit addicts; mental hospitals are not suitable for many reasons. There are no institutions established anywhere in India and the institutional treatment under expert guidance is unknown. It would certainly be advantageous if a few specialized institutions of the type of abstinence sanatoria were established in areas where the incidence of addiction is very high so that treatment could be carried out on scientific lines. There is no doubt that the public would take advantage of them. The writer's experience, so far as the treatment of addictions is concerned, is therefore limited to the non-institutional methods.

From the point of view of treatment, the drug addicts in this country are divisible into three main groups :

1. There is a large group who use opium or hemp drugs in small or very moderate quantities. The majority of these have started the drug after the middle period of their life, generally for some minor disease or ailment. They usually start with a small dose and do not increase it. The narcotic and the euphoric effects of the drug have no attraction for them; indeed they are not produced in this group at all. The habitués thus have no temptation to increase the dose, in fact they fully appreciate the evil effects which would result from it. Most of them are good and successful citizens and carry on their daily work quite efficiently. The writer has known numerous persons who

have taken small doses of opium or hemp drugs for 20 or 30 years without any apparent harm. As a matter of fact it would appear that the drug was doing them good as its stoppage made them ill and prevented them from carrying out their ordinary work. It stands to reason that, when a person can lead an active and useful life on fixed and unchanging doses, there can hardly be any mental or moral deterioration. Treatment in this large group would appear to be quite unnecessary. Some of this group, however, gradually increase their doses and suffer from the toxic effects of the drug. In such cases only, treatment is desirable and is wanted.

2. The next and a very large group consists of those who owe their entry into the paths of addiction to the association with and the example of other addicts, and to no other reason. Some of these are normal individuals who are anxious to be treated, and they respond quite well to treatment. A proportion, however, start the habit from idle and vicious seeking after new sensations; they take the drug for its pleasure-giving effects and for sexual stimulation; these people are generally found in large towns. Many of them have some defect in their character and mental make-up, and appear to be engrossed in furthering their indulgence and increasing the dose. They also have a tendency to indulge in more than one drug at the same time, e.g., alcohol and opium, alcohol and cocaine, alcohol, opium and hemp drugs. This class of vicious addict is the most difficult from the point of view of treatment. Fortunately this type, which is more in evidence in western countries, is not commonly met with in India. The few that exist belong generally to the rich and indolent classes. They do not seek treatment and nothing short of forced confinement in a special institution, and prolonged training and reconstruction of character, will restore them.

3. There is the third smaller group of habitués who have started using the drug in an attempt to tide over a period of special strain or gross overwork and fatigue. This class of addict is the product of large towns and their percentage is not nearly so high in India as in the west. This is the class who are anxious to get rid of the habit, are easily amenable to treatment, and do very well even under non-institutional treatment.

PROPHYLAXIS BY THE MEDICAL MAN

The importance of prophylactic measures in preventing drug addiction is appreciated by the medical profession in India and most habit-producing drugs are used with great care. While an analysis of the histories of drug addicts in western countries shows the medical man has been unwittingly responsible in starting addiction in a large number of cases, in India the writer has not come across many cases in

which addiction to opiates or hemp drugs could be attributed to their use by the medical practitioners in the first instance. With cocaine and morphine addiction, however, this has occurred quite frequently. In India, where addiction to crude drugs is in vogue and the alkaloid addiction so far as opium derivatives are concerned is uncommon, the importance of prophylaxis by the doctor does not play such an important part as in western countries. The stringent restrictions imposed by the Government on the distribution and sale of narcotic drugs (opium and its derivatives and cocaine and its derivatives) has to some extent safeguarded the spread of alkaloid addictions. Such drugs are not allowed to be sold except when prescribed by a qualified medical practitioner; the dispensing chemist has to keep a careful account of every grain of the drug sold, in books kept for the purpose which are frequently scrutinized by the authorities.

TREATMENT OF OPIUM ADDICTS

Sudden and gradual withdrawal.—The withdrawal of the drug by the 'sudden method' advocated by Bonhoeffer has been recognized to be scientifically the best method of treatment in many countries. In spite of the success achieved with it in Europe and America it has not been possible to carry it out in India. The writer has tried the method, but has met with little success. The reason is that the conditions under which the cases were treated were far from ideal. There are no specially-equipped institutions in this country where addicts undergoing this form of treatment could be housed and could have all the facilities to help them through the critical period of abstinence symptoms. The post-withdrawal insomnia and the digestive and other troubles are extremely distressing and need efficient handling. Some of the writer's cases had to be treated in the wards of an ordinary hospital. Some were treated in their own homes where the success of such a treatment was doubtful from the beginning. The writer's experience, therefore, with regard to the 'sudden withdrawal' method is limited and unsatisfactory from every point of view. Although he has no personal experience of such treatment in special institutions, he has no hesitation in saying that, so far as Indian addicts are concerned, the sudden withdrawal would imply a period of frightful physical and mental suffering and trial which the majority of them would be unable to bear. The shock of sudden withdrawal would be too much for many of the addicts and even those with strong will-power determined to get rid of the habit will stand it with difficulty. It would make the most willing and determined of them lose confidence and they would end by refusing to go through the treatment. Their sufferings would make them lose their faith in

the treating physician, and they would become distrustful and hostile so that it would become difficult to establish friendly relations or to inspire confidence in them. The writer has often heard inveterate opium eaters remark that they would rather endure hell than the abstinence symptoms. Experience in India is in accord with that of many authorities in the west who consider that the patients subjected to harsher methods of treatment, such as locking them up and letting them 'suffer it out', are the very ones that are more likely to relapse and go back to the habit. The above remarks apply to the opium addicts only. In the case of hemp drugs, cocaine, alcohol and chloral hydrate, sudden withdrawal can be carried out under non-institutional conditions without any great difficulty.

The writer has met with a great deal of success with the slow or gradual withdrawal method. There is no doubt that whether the process of withdrawal is gradual or sudden, a great deal of suffering has to be gone through by the patient. Administration of no amount of other drugs will completely eliminate the distressing symptoms of abstinence. With the gradual method, however, the pain and discomfort of actual withdrawal are reduced to a minimum. If due attention is paid to the psychological side of the treatment, the patient is made to believe that the physician thoroughly understands his trouble and is doing his best to relieve him of his sufferings, and the chances of a permanent cure are greatly enhanced. The patient may even carry not unpleasant memories of his restoration period. Another advantage is that the post-withdrawal insomnia, which is an extremely distressing condition, is much less frequent. Moreover, under conditions existing in India, it appears to be the method of choice. If the withdrawal is affected with reasonable celerity and with as little discomfort to the patient as possible, it will encourage other sufferers to seek the treatment and those who have relapsed may also return. While it cannot be said how long it would take an Indian patient to be cured if he were to undergo treatment in an institution with the sudden withdrawal method, the experience of many European institutions is that at least three months' stay is necessary. The adoption of such a treatment will, therefore, be very expensive for a country like India. The writer's experience is that with the slow withdrawal method it takes three to six weeks to effect a cure in most of the Indian addicts who are going to be cured. The decrease in dosage is carried out very gradually at first so that it is imperceptible. After a few days it can be effected more rapidly, especially if some pill such as that containing nux vomica, gentian and black pepper is given as a substitute. The substitution is started with the morning dose at first, leaving the evening dose untouched,

this procedure prevents insomnia. Minor symptoms such as diarrhœa, epigastric pain and nausea may be met by giving ordinary alkaline mixtures. Usually in three to four weeks the drug can be entirely stopped.

It cannot be denied that in spite of all precautions a large number of failures result. In many cases when it was hoped that all was going well, it was suddenly discovered that the patient was secretly obtaining a supply of the drug. The ingenuity shown by the addicts in this connection and the extraordinary way in which they evade those on guard is amazing. The chances of the treatment being prematurely suspended are also great. Even by the slow method the withdrawal cannot be effected except by exercising a good deal of compulsion. Most of the patients start with good resolutions but give in about the second or third day when the symptoms are very acute. To keep control over such patients under ordinary hospital or home conditions is very difficult indeed. With full knowledge of all these difficulties the gradual method has been tried under non-institutional conditions with a fair degree of success, especially in addictions of short duration. Considerable care and attention has to be exercised in the selection of cases. Before starting the treatment the patient must be thoroughly examined and any physical conditions which may have led to addiction, e.g., septic foci, must be treated. Duration of addiction is an important factor; cases under 5 to 7 years taking 10 to 15 grains daily are generally amenable to treatment. In many persons taking over 20 grains daily for prolonged periods, circulatory disturbances leading to collapse are likely to supervene if the drug is suddenly withdrawn. Sudden withdrawal is successful and is recommended with addicts taking under five grains daily.

The gradual withdrawal method is also suitable for mass treatment of opium addicts. The writer during the Great War in the East African campaign was in medical charge of a Sikh company of sappers and miners, about 200 strong, from a state in northern India. Most of the Indian officers and men of this unit were heavily addicted to opium, many taking as much as 100 grains daily and some over 200 grains. The unit in the beginning brought a certain supply of opium with it, but this was soon exhausted and men had to fall back on the commissariat supply of 5 to 6 grains daily. With the help of the officer commanding the company the writer had no difficulty in cutting down the dose to a few grains a day, in a month's time, without any of the men showing signs of distress. They gladly went through the cure and some of them gave up the habit entirely. As there were no towns near, the chances of anyone obtaining local supplies were completely eliminated.

The writer has shown that there is a pre-dominant psychic element in opium addiction and the production of abstinence symptoms. He has come across cases of persons addicted to large doses of opium (20 to 100 grains a day), who have been sent to a jail for some criminal offence and their supply was inevitably stopped; they did not however suffer from very marked symptoms of abstinence. During the treatment of addicts to rid them of opium habit, the drug can be largely or totally replaced by substances such as gentian or nuxvomica in pill form without the patients realizing it. Further, if the patient is not aware that he is taking opium, the drug can be effectively given for weeks or months for its therapeutic effects, without producing addiction or abstinence symptoms. A great deal can be done by getting the co-operation of the patient, and proper attention to the psychological side of the treatment ensures success in many cases.

Infantile administration of opium.—The habit in infants and children is not difficult to break. In the usual course of events the parents continue to give the drug up to the age of two or three years and then, when the child can take care of itself, it is stopped. Both the gradual and sudden methods of withdrawal have been tried with an equal degree of success, but it is better to adopt the sudden method. The psychological element plays a very minor part in children and as a rule there is little discomfort. The withdrawal symptoms met with are looseness of bowels, diarrhœa, and irritability of temper, and in severe cases loss of appetite, nausea and abdominal pains also occur. Diarrhœa can be easily controlled by powders containing sodium bicarbonate, bismuth carbonate and aromatic chalk. In severe cases with mental irritability, a bromide mixture with a few minims of tincture of belladonna may help to quieten the patient. The child gets quite well in a few days and a cure is affected; no after-treatment is as a rule necessary. Even the worst cases with marasmus and emaciation begin to put on weight soon after they are rid of the habit.

Opium smoking.—The experience in India is that opium smoking is more difficult to cure than opium eating. Fortunately owing to very strict regulations the habit of smoking opium is now rapidly disappearing from many parts, though it is still prevalent in Assam. The writer's experience of its treatment is very limited, but there appears to be little doubt that an opium smoker is much more attached to the drug than an opium eater. It would appear that although smaller quantities of the alkaloids are absorbed (most of them must be destroyed by heat), the absorption is very rapid from the large surface of the capillaries of the lungs and the respiratory tract, and the effects are sudden and more intense resembling an

injection of morphine. The treatment of opium smoking has not been properly worked out in India. Some authorities allow the patient the drug by the mouth and gradually cut down smoking. Once eating is successfully substituted for smoking, the addict becomes more amenable to treatment.

Post (unlanced capsules of P. somniferum).—It is the common belief among the addicts that *post* does less harm than opium. The writer's experience, however, is not in accord with this view. A person addicted to poppy heads requires comparatively much larger doses of opium to produce a similar effect; moreover the physical and mental effects produced by ordinary doses of *post* are much more marked than with moderate doses of opium. This in all probability is due to the potentiating effects the constituent alkaloids of poppy capsules have for one another. It is more difficult to get rid of this habit than of the opium habit. The sudden method is rarely practicable in these cases, the gradual method being the only one which meets with success. The dose is gradually reduced by half a capsule till a fourth of the original dose is reached and then it is stopped entirely.

Hemp drugs.—The treatment of hemp drug habit is not at all difficult, though it is easier to cure the eating habit than the smoking habit. Withdrawal symptoms as they are met with in the case of opium addicts are hardly ever seen, indeed the patients find no difficulty in giving up the habit of their own accord. In northern India many people indulge in *bhāng* drinking in the hot weather, on account of its cooling and refreshing effects, and give it up in the winter quite suddenly. Hemp preparations when taken habitually by the mouth can be suddenly withdrawn without any marked untoward symptoms. Temporary loss of appetite, constipation lasting for a few days and rarely palpitation and restlessness may occur; all these can be easily dealt with.

Charas and ganja are stronger preparations and, as they are generally indulged in by smoking, their effects on the system and particularly on the nervous system are more pronounced. The will-power of the smoker is weakened and without the physician's help he is not able to give up the habit. Treatment in special institutions with facilities for forcible withdrawal is likely to give the best results. The psychological and mental treatment, and training and education of the addict are as important in the case of hemp drug smokers as in opium addicts, in spite of the fact that considerable physical pain accompanying withdrawal is absent.

Cocaine.—The habit of eating cocaine is easier to cure than that of injecting cocaine. Removal of the addict from the environment

in which he has learnt the habit and from associates in whose company he indulges in the drug, preferably to a place where he cannot get it, often effects a cure. The writer knows of many instances where the individuals from one part of the country went for a few months to another part where they were unable to get the drug and where there were no associates; they were able to conquer the craving for many months at a time without difficulty. When, however, they returned to their old surroundings they again succumbed to the temptation. Similar facts have been observed in addicts who have been kept confined in prisons. They are able to give up the habit during confinement and go for years without the drug; but they generally take it up again after discharge. The writer is convinced that cocaine eating is comparatively a much milder form of indulgence than cocaine injecting.

Psychotherapy and mental training are important; the psychological rearrangement of the personality by finding some innocent emotional compensation will often help the habitué to give up the habit. The drug must be withdrawn all at once and symptomatic treatment given for the withdrawal symptoms. Next to the opium habit, the cocaine habit is the most difficult one to cure in India.

Auxiliary treatments.—Atropine and hyosine have been tried in the earlier stages of withdrawal of opium, and strychnine in the later stages with good results. The belladonna-hyoscyamus mixture recommended by Lambert is useful in that it lessens the shock, decreases diarrhoea, and relieves insomnia. Gastrogenous phenomena are not marked in the treatment of the opium habit, as they are with morphine, and alkaline and acid treatments are not necessary. Adrenaline and ephedrine have been tried for mitigating the withdrawal symptoms in a few cases with good results. It is rarely necessary in this country to use sedative drugs, such as codeine, narcozan, luminal, sodium amytal and pernocton, in the gradual withdrawal treatment of opium eaters and the writer has no experience of the use of these drugs.

Insulin treatment.—Insulin alone or with grape sugar has also of late been tried in Europe. Sakel (1930) used insulin alone in doses up to 80 units in 24 hours to combat withdrawal symptoms in cases where morphine was cut off abruptly, with satisfactory results. F. Braun administered bigger doses of the drug and in addiction employed soporifics like luminal. The author has tried this method with good results.

So far as opium eating is concerned he has carefully tested the effects of the drug on the blood sugar of both diabetics and normal Indians. Small and moderate doses of opium have little or no effect on the blood sugar of

individuals who are not suffering from disturbances in carbohydrate metabolism. In persons whose blood-sugar content is abnormally low, opium may raise it. The blood sugar in the early and mild types of diabetes may be actually reduced. It is only in the severe forms of the disease that the blood sugar is actually raised. In some patients opium does no more than raise the renal threshold of excretion. The writer's findings with regard to opium agree with those of Simenauer and Pulfer, and Anton who found that in human beings, as opposed to animals, morphine produces little or no disturbance of the carbohydrate metabolism.

The utility of diuretics such as novasural and eufhyllin in the slow withdrawal method is doubtful. The writer's observations show that in addicts taking moderate and large doses of opium there is retention of fluid in the blood; in those taking small doses, however, the output of urine is actually increased and the blood fluid is not altered. When the kidneys are damaged and there is albuminuria, the administration of 1 to 9 grains of opium daily produces an appreciable decrease in the quantity of urine passed and in none of the cases are there indications of added damage to the kidneys, which the drug is reputed to cause in such cases.

Vesicatory serum therapy of Modinos in opium addiction.—The method is very simple, cantharides cerate plaster to a size of 8 square centimeters is applied to the patient's chest or abdomen, and after 16 hours serum varying from 2 to 8 c.cm. is taken and reinjected into the upper part of the arm or leg. The operation is repeated on the third or fourth day, and the third injection is given 4 to 6 days after the second injection. The dose of the narcotic is rapidly reduced and may be completely cut off within 3 to 7 days. It is believed that antibodies are formed which create a distaste for the drug but this view is not universally accepted and distaste to the drug is attributed to the production of hypersensibility. Other authorities, like Noordhoek, say that the so-called hypersensibility is not specific but is merely psychological and may be obtained by merely injecting common salt solution. He further states that relapses after the treatment are as common as with other methods.

The writer's own experience with this form of treatment is limited, but the method is being tried in the treatment of opium addicts in Burma jails. Opinion among the medical officers trying the treatment is unanimous on one point, namely that one or more injections of the autoserum from a blister make the addict sensitive to opium. The patients say they do not wish to take opium any more, not because they do not like it, but because the consumption of the drug even in small quantities does not produce the pleasure or exhilaration that it used to produce before. On the contrary the

effects produced by a dose are unpleasant, and heaviness of head, nausea, vomiting, etc., are produced. A distaste for the drug is thus developed and as euphoric effects are not produced opium is not wanted. A control experiment was also tried in the following manner. Some addicts were blistered in the usual way and the fluid from the blister was removed. Instead of the fluid from the blister being injected, in a number of cases injections of normal saline were given. It was found that the addicts who had normal saline did not respond in the same way as those in whom actual serum was injected. In other words, mere blistering did not do any good so long as the serum was not reabsorbed; nor were the effects due merely to the psychological effects of the injection. It is at present difficult to say how long the sensitiveness to the drug of addiction will last, but investigations on this subject are being carried on. It must be remembered, however, that most of the addicts were prisoners under prison discipline and living under conditions in which temptations by way of easy access to opium did not exist. In one of the jails the treatment was tried on two warders who were free to go about and could easily obtain opium if they so desired. In both cases the injections of serum produced the same effects as in the prisoners.

Whether the treatment will eventually produce a permanent cure or not is difficult to say with any degree of certainty but the results so far obtained are certainly striking. The patients gained in weight after the treatment, the appetite returned and the general health improved in a remarkable manner. The following provisional conclusions can be drawn from the data so far obtained:—

(1) That the treatment with vesicatory serum injections is a valuable measure in the treatment of opium addicts.

(2) That probably addicts who have any will-power left will be completely and permanently cured of the habit through its agency.

(3) That probably those who have no will-power left, although they may be temporarily benefited, will relapse as soon as they have the opportunity.

It is believed that about 50 per cent of addicts could be cured by this method.

Lecithin treatment.—Lecithin treatment of opium addicts has been mentioned by Ma (1932) and is being tried in India by the author. From certain observations made on the physical properties of the blood sera of such addicts where it has been found that the protein content, specially the neuro-proteins, is lacking or deficient, particularly during the withdrawal period, the rationale of this treatment can be understood. Ma (1932) from a cytopathological study of chronic morphinism in albino rats found that the withdrawal of the drug in

the addicted animals led to severe pathological conditions of the Golgi apparatus in the cells of various organs. Without treatment these conditions are overcome in 10 to 12 days. Feeding with lecithin, on the other hand, for a period of six days before and for some days after prevented the Golgi apparatus from becoming abnormally reduced; this was accompanied by a condition of general well-being of the animal which was absent in those receiving no lecithin. The treatment has been tried in China on 143 opium smokers. In addition to their ordinary diet the patients are given 6 to 9 eggs per day to enrich the diet in lecithin. The bouts of craving are overcome by administration of tincture of opium in small doses. The lecithin given is prepared from eggs and made into pills with glycyrrhiza powder. The usual daily dose is 4 to 6 grains. It has been found in most of the cases that lecithin, although it prevents most of the untoward symptoms, is insufficient to combat all the withdrawal symptoms, alone. This method of treatment is now being tested in Indian addicts.

After treatment.—The importance of psychological aspects of the treatment of drug addicts has already been stressed. The responsibility of the physician does not end after the drug is withdrawn. The period following the withdrawal is most critical and dangerous and unless great care is taken relapses may occur. The whole of the nervous system has been strained and a thorough reconstruction and rehabilitation of the personality and the character of the addict is imperative if a permanent cure is desired. The physician can do much by way of encouraging the patient and making him believe that by his will-power and firmness he will get rid of the habit. A common belief among Indian addicts is that elimination of the drug habit will leave them sexually impotent. There is no basis for such a belief and the patient should be fully assured that the loss of sexual desire which they observe after giving up the drug is a temporary phenomenon and is a part of the general loss of tone of the organs. It usually passes off in 4 to 8 weeks, but rarely it may last for several months. During the period following withdrawal a good tonic in the form of iron, arsenic and strychnine is very helpful. Occupation therapy is also very important. As soon as possible the patient should start doing some work so that his attention is diverted in other directions. He must lead a quiet life and avoid excesses of all kinds for a year or more after withdrawal has been successfully effected.

THE surgery of 100 years ago consisted for the most part in the somewhat barbaric removal of offending members; for operations had to be rapid, and being always septic had to be followed by open wounds. In the absence of anaesthetics and antiseptics, anything beyond the removal of disease was almost impossible. The introduction of anaesthetics increased the

time available for operating, but for many years little was attempted save removal of diseased parts. Antisepsis and asepsis made possible the suture of the wound, and thus paved the way for plastic and abdominal surgery. But for a time operations were still mainly concerned with the removal of diseased organs or limbs, until in recent times, when surgeons have taken more heed of the constructive side of their work. Recent advance in surgery has thus been along two chief lines: (i) physiological surgery, such as the excision of the pyloric end of the stomach to prevent gastro-jejunal ulcer by decreasing gastric acidity, or hemi-thyroidectomy in Graves' disease, and (ii) reparative surgery, such as plastic and orthopaedic operations, tendon transplants, nerve suture, and the rest.

In regard to malignant disease, we have not yet progressed beyond the stage of mutilation. The disease must go, and the operation for its removal must be radical; but the continued advance of knowledge has modified somewhat the extent of our mutilation, and in this paper I propose to describe certain aspects of the surgery of malignant disease in which structure and function can be preserved although the disease itself is radically dealt with. Radium and x-rays are of course the weapons which in recent years have enabled us to preserve limbs and organs which formerly had to be sacrificed.

Malignant disease in limbs

Dr. Vail, of Miraj, wrote a paper on the conservative treatment of sarcomata of bone and similar conditions some 7 or 8 years ago. Before and more especially since reading that paper, I have always attempted to avoid amputation, if it can be avoided consistently with the saving of life.

The danger of sarcoma is not in the immediate neighbourhood of the growth, but is in the blood stream; and it is quite certain that the prognosis of the life of the patient is just as good after a local excision is done—provided it is radical—as it is with amputation, except for one factor, and that is the possibility of dissemination of the malignant cells during the operation itself. To minimize this, I invariably give the sarcoma patient a full course of deep x-ray therapy to the growth and its immediate neighbourhood before operation. Five minutes of 5 milliamps at 5-inch spark gap (90,000 volts) every day for 10 days (screened with 1 millimetre aluminium and with the target at 15-inch distance) is a sufficient dose, and can be given with only a moderate-sized x-ray apparatus.

The following precautions should also be taken:—

- (1) Preliminary radiograph of lungs, to exclude the presence of secondaries.

(2) Gentle handling of the growth during operation.

(3) Spinal anaesthetic (8 to 10 c.cm. of 1 in 1,500 percain) for the lower extremity.

(4) Application of a tourniquet when anatomically possible, to cause stagnation of the circulation, minimizing the spread of sarcoma cells.

(5) Radical excision of the growth, including its true and false (i.e., fascial or muscular) capsule. If any important nerves have become adherent to the growth, radium needles can be left alongside them, being placed there at the time of operation. I generally leave 1 milligramme of radium per $1\frac{1}{2}$ centimetres of nerve tissue, for a week. Radium of similar dosage can be left in the place from which the sarcoma is actually growing, such as the periosteum, or the origin of a muscle.

In cases of periosteal sarcoma, there are two possible ways of dealing with the bone. One is by radium as already indicated; the other is by excision of the segment of the bone from which the sarcoma is growing, with replacement by bone-graft, using the fibula as a graft for the femur or humerus, and tibial grafts for smaller bones. I have followed both these procedures with success in various cases both in arms and legs*. In cases of endosteal sarcoma, the portion of bone involved, as ascertained previously by a good radiogram, must be removed with about three-quarters of an inch of healthy bone on each side, and the bone must be replaced by a graft (except in the case of an upper radius, lower ulna, or upper fibula); see plate II, and figures 5 and 6.

All muscles involved in the growth must be radically removed. The nerve supply of those

* Two femora, 5 ulnae, 2 radii, 1 tibia, and 1 fibula showed no recurrence of round-celled sarcoma within 1 year or more. Unsuccessful cases:—1 femur (secondaries in lungs), 1 ulna (local recurrence, followed by amputation). Cases of less than a year:—2 femora, 2 humerus, 1 tibia and 1 ulna.

DESCRIPTION OF PLATE II

Fig. 1.—Myeloma of tibia before operation. Tibia was cut across just below growth, and its upper end removed. This necessitated the removal of some three inches of the fibula, which was used as a graft to unite the tibia with the end of the femur, the external condyle being used for this purpose for greater stability.

Fig. 2.—Myeloma of tibia after operation. Shows insertion of fibula graft, and reinforcement by Lane's plate. This patient was seen many months later walking about rapidly, in spite of the shortening.

Fig. 3.—Myeloma of lower end of femur. This was scraped out and treated conservatively, there being enough of the bone left to support the weight of the body. To prevent any deformity at the joint, however, a plaster-of-Paris splint was worn for the first six months.

Fig. 4.—Endosteal sarcoma of femur. Treated similarly to the tibia in figures 1 and 2. Patient went out of hospital fit, but has not been seen since.

PLATE II

Fig. 1

Fig. 2

Fig. 3

Fig. 4

muscles which are left must be carefully preserved if possible. It is surprising what good preservation of function in a limb is possible when a number of muscles have had to be sacrificed; judicious tendon transplantations may have to be done in some, but not by any means in all cases.

After the operation, I invariably give a course of x-ray treatment (as outlined above), as soon as the skin has healed, to the region where the growth was situated.

In cases of myeloma, it is sometimes necessary to remove the bone just as in an endosteal sarcoma, but allowing less margin beyond the macroscopic edge of the growth as seen in a radiograph. But if there is some strong bone left, the myeloma should be scooped out thoroughly and carefully, and its bed canterized with pure carbolic acid (not with heat nor by radium, both of which destroy osteogenetic cells). Grafts, if necessary to support the bone, can be put in six months or more after the wound has healed, and usually 'take' very well in these cases; see Plate II, figures 1 to 3.

In cases of multiple myeloma or fibrocystic disease, parathyroidectomy must be done.

In abdominal sarcomata, excision is to be done where possible, but, when preliminary diagnosis has rendered the presence of sarcoma probable, deep x-ray therapy should precede the excision and may have to be given after the excision also.

A simple-looking rounded retro-peritoneal sarcoma is often quite inoperable, whereas a more complicated growth may be fairly easy to remove. One patient of mine two years ago had a sarcoma growing from the jejunum about six inches below the flexure. It was found to be firmly attached to the left kidney, but the mass of growth—plus kidney—was freely movable in relation to the posterior abdominal wall, and was excised together with two feet of jejunum with comparative ease. This mass was considerably larger than a large grapefruit, and would have been a difficult tumour to treat with x-rays, but preliminary x-ray treatment, excision, and post-operative x-ray treatment were performed, and convalescence was uneventful. The patient reports every six months for further examination; there is at present no sign of recurrence (2 years).

Many cases of abdominal sarcoma are treatable by x-rays, and in a fair proportion they can be destroyed or at least rendered inactive. I have a case of sarcoma of the uterus who is being kept alive by 6-monthly x-ray treatment; the growth shrank up to one-third its size during the first two months, and has been kept at this size by deep x-ray therapy for three years, though it still tends to grow if left to itself, shrinking after each course of x-rays.

In many cases, however, nothing can be done against abdominal sarcoma; efficient x-ray

therapy produces fatal histamine shock, while inadequate therapy is no good.

Figure 5—Non-osteogenetic periosteal sarcoma of radius. This was treated by free excision, the bone being bared, but no bone being removed. Radium used on the surface of the bone from which the tumour had been growing, in addition to full doses of x-rays before and after operation. No recurrence in 18 months.

Carcinoma

Here radium is our great stand-by for the avoidance of mutilations, and its use need not here be described in detail. But in my opinion it should only be used for carcinoma of the soft parts, and not in any cases involving bone. For cancer of the lower jaw (and usually the upper jaw also) radical excision is the only justifiable line of treatment in most cases, for if radiated they develop osteomyelitis, which leads to necrosis of bone and is very slow in healing, and very painful. But in cancer of the cheek, tongue, or lips, useful organs may be preserved and prolonged plastic procedures dispensed with if radium be used.

The question of carcinoma of the breast is still discussed in circles where radium is available, but my personal view—to which anyone whose supply of radium is limited will probably subscribe—is that in all cases of undoubted carcinoma of the breast the full radical operation should be done, including all glands up to

the clavicle and both pectorals, radium being used for mediastinal or supraclavicular glands, or other places according to the operator's judgment, such as places where enlarged glands have been found or have been adherent.

Figure 6.—Final stage of a case of sarcoma of lower end of tibia. The growth was endosteal, in the lower end of the shaft. A piece of tibia was excised including the growth and a small margin of healthy bone on each side. This left an extremely small piece of tibia for the articulation, less than one-quarter of an inch thick. A small tibial sliding graft was inserted into the gap about six months after the first operation. The fibula was straightened and shortened, two small wires being placed around it at the site of the mortise. The graft and the lower end of the fibula both slowly increased in size, and six years after the first operation the radiograph here reproduced was taken, showing how firmly the graft has united with the lower end of the tibia, and how thick it and the fibula have become, the latter having burst the wires which surrounded it. The patient is walking long distances without tiring, the leg being $1\frac{1}{2}$ inches shorter than its below. The patient was 16 years old at time of operation, and is now 23.

Carcinoma of the uterus is 'treatable by radium if it is operable by Wertheim's hysterectomy'. If it is inoperable owing to direct extension, radium is sometimes worth trying. If it is inoperable because of extension to glands, it is in my opinion very seldom justifiable to attempt removal either by operation or radium.

Nevertheless a laparotomy should be done; firstly, by it we may discover the growth to be operable, or more probably treatable by radium followed by operation; secondly, if it is inoperable the patient is going to have a miserable death which it is our duty to make as merciful as we can, and this we can do by the removal of the hypogastric plexus (nowadays known by those who have forgotten their physiology as the pre-sacral nerve or nerves). A complete clearance of the front of the last lumbar vertebra between the peritoneum in front (to which the nerves are often adherent) and the anterior common ligament behind, and between

Figure 7.—Three typical cases of sarcoma of the ulna, all dealt with by local removal.

the two divergent common iliac arteries and veins on the two sides, will deal effectively with about 90 per cent of the pain which the unfortunate victim is going to have before her death. The bladder pain, if present, is not usually controlled nor prevented by this operation, but the sacral sympathetic branches to the bladder (the so-called pelvic nerves, bilateral and going along the utero-sacral ligaments) are usually unattainable in an inoperable growth, and very difficult to find in any case; some operators say they have dealt with the pelvic nerves by alcohol injections into the utero-sacral folds. Pain involving the sacral somatic nerves is likewise unrelieved by hypogastric neurectomy, but this simple ablation of the 'pre-sacral' nerve ought in my opinion to be done in every case of uterine cancer in which the abdomen is opened. In a case with much pain its results are really impressive. A patient of mine who had had no sleep for 5 weeks slept soundly for 4 days and nights after removal of the hypogastric nerves, and that in spite of the fact that pain in the bladder and down the legs had already been complained of, and the true pelvis was already full of growth up to its brim. In several other cases with intense pain, the pain has disappeared completely after this simple

DURATION AND DEGREE OF IMMUNITY AGAINST SMALLPOX CONFERRED BY INFANTILE VACCINATION

Ry J. L. PINTO, D.F.H.

Director, Government Vaccine Institute, Belgaum,
Bombay Presidency

THE question of duration and degree of immunity against smallpox conferred by primary or infantile vaccination is certainly of very great interest, from both the theoretical and practical points of view. The importance and advantages of infantile vaccination are almost universally recognized and admitted. In most countries vaccination of infants is enforced to a greater or smaller extent by legislation or otherwise. Though this measure in protecting one against smallpox is rather extensively adopted, it is to be noted that infantile vaccination does not protect an individual permanently. The immunity conferred is only for a limited period. Experiments and experience have shown that the protection it affords, though absolute for some years, gradually wears off almost completely. It is therefore in view of this fact that though in vaccination we have had a most effective weapon against smallpox for the last 150 years or so, since Jenner discovered it in 1796, this epidemic disease still prevails throughout in some form or other. It must be admitted, however, that though primary vaccination alone does not afford full protection, it has even then a considerable effect against the epidemics of this disease. The great fall of smallpox morbidity throughout the world, as compared to the pre-vaccination days, is certainly to be attributed to the vaccination in general. To conquer smallpox effectively and protect an individual permanently against it, both primary or infantile vaccination and re-vaccinations at a proper period or interval are absolutely necessary. This point is fully realized by some countries in which both these are compulsorily enforced. But the periods fixed for the latter vary considerably. There appears to be a complete lack of uniformity about it, though it is generally believed that primary vaccination protects one for seven years.

Practices in various countries

In Germany, vaccination of infants is compulsory and re-vaccination is enforced as a rule on entering school and at the time of conscription,

(Continued from previous page)

operation. In operable cases, or cases treated by radium, hypogastric neurectomy is a safeguard against future pain should there be a recurrence. The surgery of the sympathetic system is at present only that of mutilation or extirpation; perhaps, as knowledge increases, it too will advance to something constructive, and become more physiological and less strictly anatomical in its principles.

but as a whole it is obligatory at the 12th year. In France, infantile vaccination during the first year of life and re-vaccination during the 11th and 21st years are compulsory. The same legislation as in France is in force in the Union of Soviet Republics. In Italy, vaccination in the second six months following birth and re-vaccination during the 10th year is compulsory. In Portugal, both vaccination and re-vaccination are compulsory and the period of immunity definitely specified by the law is seven years. In Japan, re-vaccinations are obligatory every five years. There is similar legislation in all countries where infantile vaccinations and re-vaccinations are enforced by law. In England, however, the vaccination law is so drafted with a 'conscientious objector's' clause, which practically nullifies the obligation to be vaccinated, resulting in a large number of people, reckoned to be at present nearly 50 per cent of children born, remaining completely unprotected against smallpox. In India, the Vaccination Act was promulgated by the Government of India in 1880. This was amended in 1909, but still it does not enforce compulsory vaccination for the whole of India. There are however several cities and towns where infantile vaccination is made compulsory. But nowhere in India is regular re-vaccination at any period made compulsory by law. It will be therefore seen that there is extensive divergence of views held throughout the world on this important point.

Even scientific observers and experts on the subject seem to hold equally divergent views. Winch contends that re-vaccination at 12 years is generally as positive as infantile vaccination. Gins, of Berlin, on the other hand states that under similar conditions he found only 20 per cent to show typical primary vaccination results and four-fifths of re-vaccinees to be sufficiently protected against smallpox. Kitisato, in Japan, found that nearly 13 per cent can be successfully re-vaccinated at the end of one year and nearly 64 per cent at the end of six years. Weil reported about 72 per cent successful re-vaccinations at seven years' interval. Both these probably have included in their successful re-vaccination also the accelerated reactions. Sergeant and Trener in 1932 analysed about 300 cases of re-vaccination. Most of these were aged two and three years, some 250 of them with scars of previous vaccinations. They found that their results were similar, whether the age periods taken were one year, 10 years or under, and over 30 years, successful takes being recorded in about two-thirds of the cases. Therefore it has been concluded that immunity is lost in about two-thirds of cases within three years. Under these circumstances it might be quite reasonable to inquire into the possible causes of these divergent views and findings by various observers. One would feel inclined to attribute this

possibly to the fact that various factors as regards vaccination and re-vaccination have been considered or accounted for from different points of view.

It is universally admitted that apart from the important factor of individual susceptibility, various others are also to be considered, specially:—(a) Technique and extent of vaccination incisions and vesiculations obtained. (b) The quality and potency of lymph used. It is common knowledge that most of these factors vary to a great extent in various countries. It is a recognized fact that the results and the immunity both in regard to degree and duration is proportional not only to the number and size of incisions made, to the extent and quality of vesicles obtained, but also to the quality and potency of lymphs used. The International Committee on Small-pox and Vaccination of the Health Organization of the League of Nations in their report of August 1928 state:—‘The best lymphs may have the most different results, according to the manner in which they are used. Next to individual susceptibility, one of the most important factors is the vaccination technique’. It might be therefore interesting briefly to discuss some of these factors.

It appears that the findings of various observers are based on the results of the primary vaccinations on infants being judged from the scars seen at the time of re-vaccinations, and the results of these re-vaccinations from vesiculations or reactions. Though it is true that there is a definite relationship between the immunity and the vaccination scars, and these do give a fairly good indication of results of past vaccination, it might also be noted that it is a rather uncertain factor, or at least not an accurate indication. The area of scars measured in a growing child is not always a satisfactory test because it is seen that they increase in size as the child grows. In this connection the following observation might be interesting to note:—

Average vesicular area of four insertions as measured on the eighth day of vaccination = 0.505 square inch or about 315.6 square millimetres.

Scar area of these on the 22nd day after the scabs had fallen off = 0.4421 square inch or about 263.1 square millimetres.

The same scar area at the end of three months = 0.483 square inch or about 301.8 square millimetres.

The same scar area at the end of six months = 0.523 square inch or about 326.8 square millimetres.

It will be seen therefore that a more satisfactory factor for accurately judging the relative results of vaccination, particularly infantile vaccination, would be to evaluate them from their typical ‘takes’ or typical vesicles, and their total area.

Technique, and nature and number of incisions.—As regards the method or technique of

vaccination, it varies considerably not only in various countries but even amongst individual vaccinators and observers. Not only cutaneous but also intracutaneous and subcutaneous methods are used. Everyone seems to adopt his own method, considering that to be the best one. Linear incisions with the ordinary scalpel or other cutting-edge vaccinating lancet is the one generally adopted in Europe. France, Spain, Italy and other countries use for the purpose a sort of nib-like cutting instrument. Force in America uses his drill method, which consists of in applying vaccine lymph to a 2-millimetre circle of derma, exposed by removing the epidermis by means of the rotary motion of a small drill held perpendicularly to the tightly-drawn skin. On the other hand Leake of the United States Public Health Services has adopted ‘acupuncture’ or the multiple puncture method with remarkable success. Both these methods are officially approved and recommended under the New York Regulations. Dudley also used the ‘acupuncture’ method at the Greenwich hospital with excellent results.

Further, it may be noted that, besides technique, both the number and the size of incisions or marks also vary throughout to a great extent. In Canada, the one-mark puncture method is officially recommended and adopted. In England, the Ministry of Health, though it prescribed no special technique or method, till recently insisted that in primary vaccination a total vesiculation area of not less than half a square inch should be aimed at. This standard of a half square inch area of vesiculation which was determined long ago by the Royal Commission on Vaccination, as a necessary requirement of primary vaccination to secure maximum protection, remains unchallenged and its effectiveness is admitted on all sides. But of late, on the recommendations of the Vaccination Committee of 1928, England has adopted the American and Canadian practice of one-mark incision or vaccination. This appears to be a sort of compromise arrived at between vaccinationists and anti-vaccinationists. It is also said to be a device to popularize vaccination by making it as little painful or incommoding as possible, and thus to induce people to resort to voluntary re-vaccinations more readily. Whatever may be the value of this measure it must be admitted that the value of the duration of immunity secured by infantile or primary vaccination is being sacrificed.

Quality and potency of lymph used.—The lymph used is also an equally varying factor. It is known that not only do the process of manufacture and the quality of lymph vary considerably but also the kind. Though calves are the usual vaccinifers, other animals like buffaloes, asses, sheep, etc., are also employed. Neuro-vaccine prepared from the brains of

rabbits is employed in some countries, particularly in Spain. Testicular vaccine may also be used. Vaccine lymphs in several countries are commercialized products. There is no standard of dilution, which may vary from 1 in 3 to 1 in 10. It is evident therefore that not only the quality but also the doses of vaccine virus used for the purpose may vary. It is true that all such lymphs used are expected to pass the prescribed International Standard Test. It is also seen by experiments that lymphs with much greater dilution than 1 in 10 can produce vesiculation, but this does not prove the uniform quality of lymph used in all cases by all observers. On the other hand it has not been possible so far to determine the dose or the optimum quantity of vaccine virus required to secure the desired immunity. It is the ultramicroscopic properties of this vaccine virus that makes the position of vaccination so unique and to a great extent so empirical.

Author's observation

Taking therefore into consideration all the factors discussed above, a careful investigation on the subject was carried out. It covered observations on 1,102 cases of infantile vaccinations and their re-vaccinations at varying periods. But, before stating the results of my findings, it might be of interest to note the factors and exact conditions under which it was carried out. All primary vaccinations were on infants below 12 months of age. The technique used for all vaccinations and re-vaccinations was quite uniform. In all cases (both infantile and re-vaccinations) the number and size of incisions made were absolutely the same:—four incisions in either case and of the same kind and size. All cases selected for re-vaccinations had four good scars and a record of four good vesicles seen on the eighth day of their primary vaccination. All cases were vaccinated with the rotatory vaccinating lancet which was devised and is manufactured at this institute. This lancet is used by all public vaccinators in Bombay Presidency. It is shown in the illustration below:—

is gently pressed and rotated. This results in breaking the skin very superficially in a circular incision 4 millimetres in diameter. The central needle point does not as a rule break the skin. Its main function is to fix the lancet and it, being slightly longer than the peripheral ones, serves to press the skin down and thus stretching it helps to cut it more easily by the latter. It will be seen therefore that in all my cases uniform technique and method was adopted, all incisions being of an absolutely uniform size, unlike perhaps the linear and other ones, the sizes of which are evidently judged only roughly. Further it may be also interesting to note that all my circular incisions of 4 millimetres diameter result in uniform shapes and sizes of circular vesicles between 10 and 11 millimetres in diameter.

Total vesiculation area covered by four such insertions or incisions is on an average just about half a square inch.

As to the lymphs used in all my cases, they were all manufactured in this institute and were of uniform standard of quality, potency and purity. All lymphs prepared in this institute are dermal. Heifers below two years old are the vaccineifers. A solution in distilled water of 50 per cent re-distilled glycerine of a specific gravity of 1.260 is the diluent. Dilution is in proportion of 1 in 5 by weight. Purification of lymphs is by the chloroform vapour method. They are not filtered. All lymphs are tested bacteriologically for their purity. They are also tested for potency according to the recognized international standard tests and also by special tests used in this institute. The lymphs issued from this institute are reported to give nearly a 100 per cent success rate. From the result statements submitted by public vaccinators throughout the whole Bombay Presidency, including Sind, from 763,610 primary vaccinations done by them during the last year, a case success rate of 99.96 per cent and insertion success rate of 99.46 per cent are reported. Also all my vaccinations and re-vaccinations were carried out by the same two vaccinators of this institute. All results of vaccinations

Rotatory vaccinating lancet (actual size), Belgaum Vaccine Institute pattern.

The circular disc end is provided with five tiny conical-shaped needle points; four of these are on the periphery of the disc and one very slightly longer than the others in the centre. The tiny scoop on the other end of the lancet is used for the purpose of placing a drop of lymph on the area to be vaccinated. Through the drop of lymph thus applied on the skin, the disc end of the lancet, held perpendicularly,

were personally seen by the writer and carefully recorded. Primary vaccination results were seen on the eighth day and those of re-vaccinations generally on the sixth day and earlier. There is not much to be said or noted about the primary or infantile vaccination reactions, but the same cannot be said as regards re-vaccinations. The types of reactions of the latter may and do considerably vary from the

former. In the correct interpretation and significance of these, conclusions are to be drawn. The importance of accurate records of re-vaccination reactions therefore is obvious. More or less in accordance with the views expressed on this point by the International Committee on Smallpox and Vaccination of the League of Nations, the results of my cases have been classified as follows:—

Class I.—Definitely unsuccessful.

Class II.—Very slight reaction. Allergic or early, showing just a small papule with very slight or no areola.

Class III.—Accelerated vesicular reaction. Developing earlier than in the primary vaccination type reaction.

Class IV.—Definitely successful. Showing a typical reaction of primary vaccination type as seen on the eighth day after vaccination.

The statement below shows the results, tabulated, for half-yearly periods, of 1,100 cases of children vaccinated when they were infants and the same re-vaccinated at varying intervals, in both cases at this institute and under absolutely identical conditions. From the statement are excluded two cases in view of their exceptional results. They seem to demonstrate forcibly the individual susceptibility factor in vaccination. One child being re-vaccinated within about 10 months was found to show an extraordinarily good reaction of a definite primary type. This child was vaccinated on 7th September, 1932, when five months old and was re-vaccinated on 2nd August, 1933. Results on both occasions were seen to be practically identical. The other child being re-vaccinated within five months was found to

show also an exceptionally good reaction of the accelerated type with good vesicles and areola.

From the above figures it will be seen that, though the results obtained give on the whole a fairly definite indication of progressive march one way or the other, at some age periods this is not quite as regular as one would expect. If, however, these same results are grouped together in one-yearly periods, they furnish more intelligible data and enable one to draw some definite conclusions.

TABLE II

Showing results of re-vaccinations at different intervals in children vaccinated in infancy, grouped in one-year time periods and shown as percentages

Interval between infantile vaccination and re-vaccination	Number in group	CLASS I	CLASS II	CLASS III	CLASS IV
		Definitely unsuccessful, per cent	Allergic or early papular reactions, per cent	Accelerated vesicular reactions, per cent	Definitely successful — Primary type, per cent
1 year	158	78.30	21.70
2 years	168	62.10	31.50	5.85	0.55
3 "	215	41.25	34.95	12.55	11.25
4 "	148	28.75	36.15	15.50	19.60
5 "	160	25.45	34.55	16.10	23.90
6 "	125	17.65	28.05	15.20	39.10
7 "	126	15.95	23.95	15.95	44.15

Class I.—The figures above in this class will show that even within one year only about 78 per cent show definitely unsuccessful results; in seven years this figure gradually dropped to about 16 per cent. This drop, it will be seen, is steady and marked during the first three years, after which it becomes less definite. The possible explanation of this lies in the fact that infantile vaccination is performed in a body of small weight, about 15 to 20 lbs., which is undergoing rapid developmental changes and so the adjustment of immunizing powers which has taken place in the infant fails to meet the demands of the rapidly-growing body and tissues.

Class II.—In these cases there is no vesicle developed but only slight induration and a small papule reaching its maximum reaction between the second and fourth day of re-vaccination. It is only an allergic or papular reaction; it is not a definite indication of loss of immunity. Some observers, like Muller, even go to the extent of suggesting the reaction to be the true evidence of immunity. Anyway, it may be taken as a beginning or the first step of the backward journey on the ladder of vaccination immunity. Except on the first and sixth years the percentage figures of these cases are fairly constant.

Class III.—In this class there was a definite vesicle and some areola but the development of the reaction nearing the primary type was accelerated. It was seen at its height generally between the fifth and sixth day. A small number was found in the second year; this was more than doubled during the third, reached 16 per cent in the fourth year, and remained practically steady at the subsequent age periods. This accelerated reaction is considered by some also as a definite evidence of immunity. This is true to some extent, but I would consider it as a residual immunity in about its last waning stage and affording a poor protection against smallpox.

Class IV.—Apart from one exceptional case, referred to above, it will be noted that a definite though small number of primary type reaction begins to appear even within two years; in the third year it had reached 11 per cent, and kept on steadily and progressively rising every year. At seven years, almost half of the children that had been vaccinated in their infancy were found with no immunity left and so were definitely unprotected against smallpox.

In this connection it is admitted that opinions may differ as regards the interpretation of the above results. Generally, papular and accelerated vesicular reactions are considered by some as immunity reactions. This being so, all the cases under the above classes I, II and III would be put down together as 'immunes', and class IV as 'non-immunes'. If this classification is accepted my results would stand as follows:—

TABLE III

Showing rate of loss of immunity conferred by infantile vaccinations, percentages at different time intervals

Intervals	Immunes, per cent	Non-immunes, per cent
1 year	100.00	..
2 years	99.45	0.55
3 "	88.75	11.25
4 "	80.40	19.60
5 "	76.10	23.90
6 "	60.90	39.10
7 "	55.85	44.15

Though the above classification may be academically correct, I consider it inadvisable to accept it as a safe guide from the practical point of view. There can be no two opinions as regards the significance and the interpretation of results under class I and class IV. These are definite, but between these two extremes are to be found class II and class III. The former is a very slight deviation of class I, and it may be taken as an indication of good immunity, but the latter, though to some extent an indication of immunity reaction, is certainly one on which it would be inadvisable to

rely as a sufficiently effective protection against smallpox. For practical purposes, therefore, I would classify the above results under two categories—class I and class II may be taken together as being within the effective safety margin of protection, and class III and class IV taken together as outside this safety margin. So that there will be one group of cases taken as adequately protected against smallpox and may be considered as 'safe', and the other unprotected or not sufficiently protected and for all purposes to be considered 'unsafe'. This is shown in the table below:—

TABLE IV

Showing rate of loss of immunity conferred by infantile vaccinations, percentages at different time intervals; regrouped to conform with author's views

Intervals	'Safe' (classes I and II), per cent	'Unsafe' (classes III and IV), per cent
1 year	100.00	..
2 years	93.60	6.40
3 "	76.20	23.80
4 "	64.90	35.10
5 "	60.00	40.00
6 "	45.70	54.30
7 "	39.90	60.10

From the above figures it will be evident that more than one-third of the children between the ages of four and five years vaccinated in their infancy are in danger of contracting smallpox; similarly more than half of those at six years and nearly two-thirds at seven years. Practical application of these figures for judging the degree and duration of immunity conferred by infantile vaccination against smallpox is obvious.

Conclusion

It is an admitted fact that vaccination protects not only against smallpox but against itself. It is also known that the degree and duration of immunity conferred by it to be greater against smallpox than against vaccination itself, but, in spite of this fact, for practical purposes it would be advisable to judge the immunity from the re-vaccination results. Considering therefore this question from this angle of view and judging it from the above facts and figures it will be abundantly clear that the degree and duration of immunity conferred by infantile vaccination is certainly much poorer and shorter than is generally believed.

Gins states that about one-fifth of children vaccinated in infancy completely lose their immunity when 12 years old. Sergeant on the other hand found that two-thirds of cases lose their immunity within three years. From my investigation I come to the conclusion that in

SOME OBSERVATIONS ON THE LACTOSE-FERMENTING ORGANISMS ENCOUNTERED IN THE BACTERIOLOGICAL ANALYSIS OF WATER IN THE TROPICS

By MILITARY ASSISTANT SURGEON G. MACKEY,
D.T.M., I.M.D.

Assistant Director, Harcourt Butler Institute of Public Health, Rangoon

A CAREFUL study of *The Bacteriology of Surface Waters in the Tropics* by Clemesha (1912) shows that he mentions 29 of the 42 different species of lactose-fermenting organisms which are tabulated numerically and shown in table XII (a) (after MacConkey, 1909) at the end of that book.

The identification of the organisms contained in MacConkey's table is determined principally by their behaviour in five different sugar media, by the indol and Voges-Proskauer tests and by the presence or absence of motility. With the use of these eight tests it is possible to identify each species separately. Taylor, Martin, Naidu and Naidu (1927) gave an 'Identification table for lactose-fermenting organisms which are citrate non-utilizers or variable' (table XVII). In this table the two sugars, adonite and inulin, and the Voges-Proskauer tests as shown in MacConkey's table are omitted, so that the identification of organisms is determined by means of five tests. The same paper also contains a table showing the 'reactions of organisms isolated from different sources to the citrate, methyl-red and Voges-Proskauer tests'. The Clemesha class to which they belong is also shown (table XVI). [These two tables will, for purposes of convenience, be referred to as table XVI and table XVII.]

Table XVI contains 31 different species of organisms, eight of which, nos. 7, 36, 66, 70, 71, 97, 102 and 109, are not included in the 29 organisms isolated by Clemesha. There are therefore 23 species of organisms isolated by Clemesha and by Taylor and his co-workers. Six species of lactose-fermenting organisms additional to these 23 species have been isolated

(Continued from previous page)

the Bombay Presidency about one-fifth of the children vaccinated in their infancy completely lose their immunity within four years and about one-half in seven years. Therefore the desirability and importance of re-vaccination at an earlier interval or age period than is generally adopted in some places is obvious. Also, apart from the advisability of it being done even within one year in the presence of epidemics of smallpox, I consider it most desirable that besides infantile vaccination re-vaccination of all children as they attain the age of four or five years should be enforced by legislation or otherwise.

by Clemesha alone, and, as already stated, 8 species by Taylor and his associates, making altogether 14 species which have been isolated by one author only. These 14 species, together with 23 species mentioned above, i.e., 37 of the 42 species contained in MacConkey's table, have been isolated from different sources in the tropics.

The six lactose fermenters isolated by Clemesha alone are nos. 3, 6, 9, 33, 37 and 103, and the 23 organisms isolated by Clemesha and also by Taylor and his associates are nos. 1, 2, 4, 5, 8, 34, 35, 65, 67, 68, 69, 72, 73, 74, 75, 98, 100, 101, 104, 105, 106, 107 and 108.

Clemesha has classified 24 of these 29 organisms into three classes, according to their power of resistance to sunlight. He has left five unclassified, viz, nos. 8, 37, 69, 104 and 105.

Of the 23 species isolated by Clemesha and Taylor, 19 have been classified by Clemesha, those unclassified being nos. 8, 69, 104 and 105. The five organisms which have been classified by Clemesha additional to these 19 referred to above are nos. 3, 6, 9, 33 and 103. An analysis of table XVII shows:—

1. Eighteen species of lactose-fermenting organisms.

2. That of these 18, twelve—nos. 1, 2, 4, 5, 8, 34, 35, 72, 74, 100, 106 and 107—are included among the 23 organisms which have been isolated by the authors of both publications.

3. That, of these twelve, eleven have been classified by Clemesha, no. 8 being omitted.

4. That three organisms—nos. 69, 104 and 105—included in the group of 23 species referred to, and unclassified by Clemesha, are excluded.

5. That eight species, nos. 65, 67, 67, 73, 75, 98, 101 and 108, classified by Clemesha are also excluded.

6. That six of the eight organisms, nos. 7, 36, 66, 71, 97 and 109, already referred to are included, nos. 70 and 102 being omitted.

7. That all the organisms contained in this table give a negative Voges-Proskauer reaction with the exception of B. 97.

The water bacteriologist on completion of certain tests must refer to a table to enable him to identify the organisms isolated and has the choice amongst others of MacConkey's table or table XVII. The use of the former is advantageous in that it has a very much wider selection of organisms but the necessity of having to perform eight different tests is a disadvantage. The use of table XVII is very convenient since only five tests are necessary. The number of species of organisms contained in this table is, however, limited to eighteen and it will be noticed that, in spite of the reduction in the number of organisms, instances occur where two or even three species are grouped together and not identified singly.

For purposes of record and study of results of water examinations, it is desirable that the

organisms isolated should as far as possible be individually identified and identification in groups avoided, especially when organisms belonging to the different classes (Clemesha) occur in the same group. In order to obtain individual identification, it follows that additional tests must of necessity be carried out.

References have been made to—

(1) MacConkey's identification table.

(2) Table XVI showing 'Reaction of organisms isolated from different sources to the citrate, methyl-red and Voges-Proskauer tests'.

(3) Table XVII—'Identification table for lactose-fermenting organisms which are citrate non-utilizers or variable'.

(4) Class of organisms (Clemesha) which is also shown in table XVI.

The laboratory worker, it will be seen, is obliged to refer to different tables relating to identification, the reaction to the citrate, methyl-red and Voges-Proskauer tests and class of lactose-fermenting organisms. Undoubtedly the preparation of one table embodying the tests required for purposes of individual identification and showing the reactions to the citrate test, also the class to which they belong of certain of the more important and the more frequently encountered organisms, would be of great convenience, in that it would obviate the necessity of having to refer to different tables. The preparation of such a table however calls for careful consideration with regard to the two points, *i.e.*, the number of organisms to be included, and the number of tests required to separate satisfactorily organisms one from another with a view to individual identification.

With regard to the number of organisms to be included, since the table is required for purposes of reference in connection with routine analysis, the inclusion only of organisms most frequently found forming the bacterial population of water appears necessary along with the important species whose presence in water is significant of undesirable pollution. To avoid overcrowding and group identification, the number of organisms must necessarily be limited.

For purposes of convenience it appears necessary to consider firstly the species of lactose-fermenting organisms, which, on account of their rarity and apparent insignificance, can conveniently be omitted from the table under consideration.

In my opinion there are 11 such organisms and these are divided into three groups according to the justification for their exclusion:—

Group I.—Nos. 10, 38, 39, 99 and 110. These species have not been isolated by either Clemesha or Taylor, and on account of their rarity their inclusion does not appear to be necessary.

Group II.—Nos. 69, 104 and 105. These three species are included among the organisms shown as having been isolated by the authors of both publications. Their omission from my proposed table appears reasonable on account of the fact that they have not been classified by Clemesha nor have they been included in table XVII.

Group III.—Nos. 70, 102 and 37. The first two species are included among the 8 species of organisms already referred to as having been isolated by Taylor, and are the only two of the eight not included in table XVII. As for no. 37, this organism was isolated on one occasion by Clemesha from a sample collected from the bottom of a lake. It may accordingly be regarded as a rare finding. For these reasons these three organisms are omitted.

Excluding nos. 70, 102 and 37 referred to above, eleven species have been mentioned in one publication only, *viz.* nos. 3, 6, 9, 33, 103 (Clemesha), and nos. 7, 36, 66, 71, 97, 109 (table XVI). The importance of these eleven species lies in the fact that Clemesha has classified those isolated by him and the remaining six are shown in table XVII.

A study of these species shows:—

Nos. 3 and 33.—These two species have not been encountered in water. Clemesha isolated them from faeces in Madras and Brahmachari and Sen (1933) have done so in Bengal. Nevertheless, they are considered rare and may be excluded from the proposed table.

Nos. 6 and 9.—These two species have been isolated in Madras from lake water. The former is shown as forming a low percentage of organisms in lake waters in table IX (b) of Clemesha's book recording 'percentage of organisms in lake waters'.

The latter was isolated by Clemesha at one period of the year only, *viz.* in the 'quarter ending March'. Since they have not been isolated from any source in Burma, nor from faeces in Bengal (Brahmachari and Sen, 1933) their presence in water may justifiably be considered as an uncommon finding. These two species are excluded for these reasons.

Nos. 7 and 109.—These two species are identified together in table XVII and in MacConkey's table XII (a) with the application of eight tests it will be noticed that the reactions of the two organisms are exactly similar. To attain individual identification it is necessary to tabulate the more important of these two organisms, *i.e.*, no. 7 which belongs to group 3 (table XVI) and is usually found to be citrate —ive, no. 109 being placed in group 4 with usually a citrate + result.

B. grunthal and no. 106.—These two species are also identified together in table XVII along with no. 1. The reactions of these two organisms in MacConkey's table are not differentiated when the eight tests are used and on this

TABLE

		Lactose	Saccharose	Dulcite	Adonite	Tudol	Motility	V. P. test	Citrate	Group	Clemesha class	
1.	..	+	-	-	+	+	+	-	-	1	II	Group 1 always citrate -

100.	..	+	+	-	+	+	-	-	-	1	II	..
101.	..	+	+	-	+	+	-	-	+	2	II	..
107.	<i>B. coscoroba</i>	+	+	-	-	+	-	-	..	4	II	..

account it is necessary to omit one of the two. Regarding no. 106 Clemesha states 'next to the *grunthal* group this organism was found to be the commonest in the faeces of man and animals'. He further remarks, 'It is doubtful if this bacterium should not be in class III'. The significance of these two organisms when found in water, both being resistant types, is more or less similar and since of the two *B. grunthal* is the more common it has been tabulated.

In all therefore I suggest that 17 species be excluded from the proposed table. There remains therefore 25 species which appear to be the organisms most likely to be encountered in the routine analysis of water. These include—

(a) Nineteen of the twenty-three species isolated both by Clemesha and by Taylor and his associates, those excluded being nos. 69, 104, 105 and 106.

(b) Twenty of the twenty-four species which have been classified by Clemesha, those omitted being nos. 3, 6, 9 and 33.

(c) Six of the six species which always give the formula — + — with the three tests,

citrate, methyl-red and Voges-Proskauer, i.e., *B. coli communis*, *B. schafferi*, no. 36, *B. coli mutabilis*, no. 97 and no. 100 (Taylor, Martin, Naidu and Naidu, 1927).

(d) Twelve of the fourteen faecal bacteria which are common to Madras and Bengal Provinces, those omitted being the rarer species nos. 3 and 33 (Brahmachari and Sen, 1933). Eleven of these twelve are common to Madras, Bengal and Burma Provinces, no. 103 being untabulated in table XVI.

The number of tests required

As already stated, eight tests as shown in MacConkey's table are sufficient to enable individual identification of an organism being made. With the use of five tests as shown in table XVII it is possible to tabulate singly the following eight bacteria:—

No. 7, *B. coli communis*, no. 36, *B. schafferi*, no. 71, no. 98, no. 100 and no. 108, the remaining 17 being identified in groups of two and three as follows:—

Nos. (1, 4), (2, 5), (8, 103), (65, 66, 72), (67, 68, 75), (73, 74), and (101, 97, *B. coscoroba*).

FUMIGATION AND TRAPPING OF MOSQUITOES

By J. F. JAMES

LIEUTENANT-COLONEL, I.M.S.

Commanding Officer, Indian Military Hospital
Nasirabad

Owing perhaps to the unsatisfactory results of fumigation and spraying, measures for

(Continued from previous page)

It is very desirable that the examination should, in addition to identifying the particular organism, also afford information as to its origin, whether faecal or otherwise. In these tests, citrate, methyl-red and Voges-Proskauer are commonly used for this purpose; but the Voges-Proskauer test has an additional value for it makes possible the immediate identification of seven of the 17 remaining species referred to above.

These seven are—

B. coli mutabilis, nos. 65, 68, 73, 74, 97 and 103.

There therefore remain ten organisms which it is not possible to identify singly by means of six tests, viz, nos. (1, 4), (2, 5), (66, 72), (67, 75), and (101, 107).

In order to differentiate one from another the two organisms comprising each of the above pairs, it will be found that by the use of adonite as an additional sugar test this differentiation can satisfactorily be made, the first-mentioned organisms of each pair being adonite + and the second adonite —ive. The use of this sugar test also further differentiates *B. coli mutabilis* and no. 103.

It will be seen, therefore, that by the addition of one test to those shown in table XVII, 25 species of lactose-fermenting organisms which are most likely to be encountered in the bacteriological analysis of water in the tropics can be tabulated with their reactions, and identified singly, as a result of which it is possible to record the class (Clemesha), and the citrate group (table XVI) to which each belongs.

For facility of reference the organisms tabulated have been divided into MacConkey's four groups according as they do or do not ferment saccharose and dulcitate.

I am obliged to the Director of Public Health, Burma, for permission to publish this article.

dealing with the adult mosquito in anti-malarial work have tended to become more defensive than offensive.

The War Office report on the health of the army for the year 1931, page 111, under the heading anti-malarial measures reads as follows :—

'Fumigation and spraying are expensive measures of doubtful value. The former has been entirely abandoned.....'

While anti-mosquito must always be subsidiary to anti-larval measures, any supplementary means of destroying the adult insect if practicable is worthy of consideration. The latter gains in importance where the existence of extensive breeding grounds that are not under control, military or otherwise, interferes with efficient anti-larval control.

The method of trapping mosquitoes about to be described first suggested itself on noting the stampede of these insects through open doors and windows when pyrethrum was burnt in a room. It depends on the fact that mosquitoes so disturbed will fly towards light in an attempt to escape from irritating fumes.

A demonstration on these lines was given at Bannu in 1933 but only continued spasmodically. This year however a sharp epidemic of malaria at Wana which has an early malaria season raised the question as to whether Bannu would be similarly affected and it was decided to give the fumigation-trapping method a trial.

Large scale operations are in a comparatively early stage and it was only found possible to carry them out extensively from the beginning of October since when most barracks have been trapped daily.

After some experiments the trap described below was designed and taken to Bannu for trial. Over eighty of these are now in use and meet with considerable success.

The trap.—This is constructed by sewing a diaphragm of black cloth about six feet square at right angles over the open end of a *mul-mul* bag six feet long and twenty-four inches in diameter. An aperture of suitable size about 6 to 8 inches in diameter is cut in the black diaphragm and leads into the bag.

The trap is set by stretching the diaphragm on the wall inside a window by means of tapes and nails and leading the bag out through the window where it is attached to posts in the verandah or other available support. The cost per trap is Rs. 3.

Fumigants.—A very close comparison has been made of several fumigants the criterion being the number of mosquitoes trapped—cresol, sulphur, neem leaves, pellitory root and pyrethrum have been vaporized or burnt.

The latter, preferably in the form of one of the proprietary mosquito coils, has been found very much more efficient than anything else.

Three inches of such a coil (Katol is used in the present instance) will clear a barrack of over 10,000 cubic feet in half an hour at a cost of about a farthing. It is extremely simple to use, there is no danger of fire or of damage to metal or fabrics. The cost of fumigant per regimental unit approximates Rs. 20 per month.

Method of use.—The drill for de-infestation is as follows:—

All windows and doors except the one to be trapped which should not be on the sunlit side of the building are closed and curtained. The only light should be that through the hole in the diaphragm. Darkening and sealing barracks by means of blankets is not easy and unless care is taken mosquitoes escape through any lighted chink.

In actual practice it is far better to attach the black cloth inside the window frame and to lead the *mul-mul* bag out through the window. But it was difficult to show this in a single sketch.

The trap is set and a label placed inside it giving the name of the unit and the number of the barrack. One or two coils are lit and placed in that part of the barrack furthest from the trap. After half an hour the trap opening is tied and the traps rolled up and collected. They are chloroformed at the laboratory and the catches shaken out on to a white sheet, counted and identified. Besides mosquitoes myriads of small insects including sandflies are frequently caught and occasionally house-flies, wasps and hornets. Nets should never be fitted or sprayed and should be thoroughly aired after use.

Results.—The value of any individual anti-malarial measure is extremely difficult to determine. The number of factors involved are so many that the figures appended are only to be regarded as statements from which no conclusion can fairly be drawn. To lend force to this it is only necessary to quote the malaria admissions at Bannu for the last four years during the peak months, October and November.

Ratio per mille

	1930.	1931.	1932.	1933.
October ..	9.5	32.06	63.97	90.19
November ..	22.2	43.32	126.77	123.03

Anti-malarial measures during these years were presumably identical. The position of various lines, previous malarial history of a unit, etc., all contribute to the difficulty.

This article does not indeed set out to prove the value of fumigation-trapping in reducing malarial incidence as the results given may be purely fortuitous; what it does do however is to indicate an easy, cheap and practical way of reducing the numbers of mosquitoes and sandflies, both carriers of diseases in dwelling places in which infection is most likely to occur.

Trapping commenced on 21st September on a small scale with only a few traps. Later on, all barracks were trapped daily.

Typical counts are: *Culex* sp.—16, *Anopheles subpictus*—30, *A. stephensi*—48, *A. culicifacies*—16, and *A. listoni*—4.

More mosquitoes appear to enter barracks during the day than at night, judging by morning and evening netting, and no one species accounts for this.

The numbers caught week by week and the malarial incidence (out of an approximate total strength of 2,180) in trapped barracks are as follows:—

Week ending	<i>Culex</i>	<i>Anopheles</i>	Malaria cases
September 7th	11
14th	25
21st	36
28th	312	1,163	18
October 5th	261	1,842	17
12th	199	1,381	19
19th	283	1,257	13
26th	315	1,919	14
31st	479	2,004	10
November 7th	927	1,989	12
14th	1,488	2,034	20
21st	760	885	8
28th	451	463	14
December 5th	33	34	10

A total of about 15,000 anophelines were caught of which perhaps two-thirds were carrier species.

In conclusion I have to acknowledge the help of Captain B. T. Griffiths, I.M.S., the anti-malarial officer, Bannu, on whom the brunt of the work had fallen, and of his assistant, Jemadar Charan Singh, I.M.D.

A Mirror of Hospital Practice

A CASE OF MYELOCYTIC LEUKÆMIA WITH COMPLICATIONS

By F. McCAY, M.A., M.D. (Cantab.)

and

S. NAIRN, M.B., Ch.B., F.R.C.S. (Edin.)

Late Resident Surgical Officers, Presidency General Hospital, Calcutta

A FRAIL unhealthy little Chinese boy of fourteen was admitted to the Presidency General Hospital, Calcutta, on the 28th of March, 1931, with a four-months' history of fever and general weakness.

The fever was irregular, ranged from 97°F. to 104°F. and persisted for five months after his admission. The pulse rate rose with the temperature but was regular. On examination it was found that the liver extended to three inches below the costal margin and that the spleen was enlarged to the umbilicus. The blood picture on admission was:—

Hæmoglobin—55 per cent.

Red corpuscles—2,500,000.

White corpuscles—40,000.

Myelocytes—12 per cent.

The fundi showed typical leukæmic changes. The serum tests for kala-azar and the Wassermann reaction were negative. A trace of albumin was present in the urine. Nothing abnormal was discovered in the stools.

There were signs of fibrosis, but not of active tuberculous disease in the upper lobe of the right lung and there was pain and limitation of all movements at the left hip joint. An x-ray picture showed early tuberculous changes in the upper part of the acetabulum and head of the femur.

The left leg was rested in a Thomas' splint with the thigh slightly flexed and abducted but with no extension on account of the pain experienced. Pathological dislocation upwards suddenly occurred after two months in hospital. The dislocation was reduced under a general anæsthetic of ethyl chloride followed by open ether but the femur slipped up again directly the almost unbearable, but necessary, extension of 40 pounds was lessened. Finally, all extension was removed and the limb just supported as before. Later, both wrist joints became swollen and painful to move, but no actual bony changes could be detected by x-ray.

After the fifth month the various tuberculous processes and the fever settled down and the patient's general condition improved considerably—especially his appetite. He began to get about on a wheeled chair and to move his left leg which was now three inches shorter than the right; he also began to put on

weight steadily. Unfortunately during his sixth month in hospital he developed keratitis but this cleared up quickly under local treatment with cod-liver oil. Again in his seventh month his progress was held up by a Brodie's abscess developing in the right tibia and this had to be opened and scraped out under a second general anæsthetic.

Meanwhile his spleen had slowly increased in size and his blood picture, in spite of treatment with numerous drugs, had become:—

Hæmoglobin—55 per cent.

Red corpuscles—3,000,000.

White corpuscles—234,000.

Myelocytes—40 per cent.

Deep x-ray therapy to the spleen and long bones from varying angles was now started and continued until the white blood count had come down to within normal limits. By this time his spleen had shrunk considerably and its margin could be felt two inches above the umbilicus.

Exposures of 3 milliamperes were given at a tension of 180 kilovolts screened with 0.5 mm. copper at an anode-skin distance of 13 inches on approximately alternate days. There was considerable reaction to the first exposure of ten minutes so the remaining ten exposures were reduced to five minutes each and caused no general bad effects. The blood changes brought about by this deep x-ray therapy course are shown in the accompanying graph.

Leucocytes per c.mm. —————

Myelocyte percentage $\times 10,000$ - - - - -

When he had been in hospital for nearly a year—his parents and relations had deserted him completely—a vague fluctuating swelling appeared in the region of the displaced head of the femur and pain was experienced on moving the leg but there was no rise in temperature. Ten c.cm. and later another 40 c.cm. of blood-stained sterile serous fluid, in which leucocytes predominated, were aspirated and he soon managed to resume his hobbling about

on crutches. Two months later the swelling reappeared and was this time incised under a general anæsthetic and two sequestra removed. In the 20th month a further course of deep x-ray therapy was given as his leucocyte had risen to 200,000 per c.mm. and his spleen was again well across the mid-line. The count came down as before to within normal limits and he actually got well enough to leave hospital and go to a convalescent home for three months.

He then had to return to hospital with fever, caused this time by a *Bacterium coli communis* infection of his urinary tract. This cleared up quickly with hexamine and an autogenous vaccine course and he went back again to the convalescent home. Finally he was readmitted to hospital with high fever two and a half years after the date of his first arrival.

His spleen extended three inches across the mid-line once more and his leucocyte count was up to 480,000 per c.mm. with 54 per cent myelocytes. Broncho-pneumonia set in and he passed away after two days. Post mortem the spleen was found to weigh 18 lbs.—which in this country where so few post-mortem examinations are performed is probably a record. The case is also interesting for the tremendous resistance shown by this child to such severe diseases with so many serious complications.

A CASE OF ENCEPHALITIS PERIAXIALIS

(SCHILDER'S SYNDROME)

By H. STOTT, M.D., F.R.C.P.

LIEUTENANT-COLONEL, I.M.S.

Physician, King George's Hospital
and

G. L. SHARMA, M.B., B.S.

Demonstrator in Pathology

ENCEPHALITIS PERIAXIALIS (Schilder's disease) is rare. So far as we are aware no case has yet been reported in India.

History of the case

On the 6th October, 1934, J. A., a Mohammedan boy of 8 years, a resident of Allahabad, was admitted to King George's Medical College Hospital, Lucknow, for :—

- (1) Mental dullness—6 weeks.
- (2) Loss of hearing in both ears—6 weeks.
- (3) Loss of sight in both eyes—6 weeks.
- (4) Loss of speech—2 weeks.
- (5) Involuntary movements of the hands and feet—2 weeks.
- (6) Spasticity of both lower limbs—2 weeks.
- (7) Dribbling of urine and constipation—2 weeks.
- (8) Difficulty in swallowing—15 days.

His father stated that he himself had suffered from gonorrhœa sixteen years previously and from syphilis twelve years previously but that his son had not been ill until six weeks ago when he complained of severe headache and became unconscious. During the first two hours of the coma some involuntary movements of the face, hands and feet were noticed. His abdomen became distended and he passed a motion in

bed with much flatus, which relieved the distension. He vomited once and remained unconscious for three days, without taking food and without passing any motion. After these three days he asked for food and spoke frequently. But he remained completely deaf. This condition continued for a month when fifteen days before admission he became unable to speak. Involuntary movements in the limbs now appeared. Urine was passed in small quantities every hour or so and the bowels were never moved without a purgative. Seven days before admission the father noticed that the patient had increasing difficulty in swallowing.

Condition on admission

The young patient lies quietly in bed on one side, for the most part drowsy or asleep. He is not anæmic, nor emaciated. He does not speak, weep, cry or laugh. He cannot hear in either ear when spoken to. Vision in both eyes is lost. His eyes do not blink when a hand is waved suddenly before them. Apparently he cannot comprehend his surroundings and appears to exist without consciousness and without intelligence.

Nervous system

The pupil reacted to light. There was no squint. The eyes appeared to move freely in all directions. Both optic disc margins were blurred; this was probably due to œdema from the cerebral swelling and increased intracranial pressure. The blurring was more marked in the left disc. The lower limbs were spastic with brisk knee and ankle jerks. Babinski's reflex was present on both sides. The upper limbs were normal. Sensory functions could not be tested satisfactorily because of the patient's mental condition. Difficulty in swallowing food was noticed. Urine was passed in the bed in small quantities every hour or so. The patient will frequently abruptly throw his legs and hands in any direction. These movements appear more marked on his right side. The right hand is often placed over the right temporal region as though some trouble existed there.

Reports on blood and cerebro-spinal fluid

On the 8th October the polymorphonuclears were 60 per cent, the lymphocytes 33 per cent, the large mononuclears 5 per cent and eosinophils 2 per cent. No malaria parasites were detected. The Wassermann reaction was completely negative.

The cerebro-spinal fluid was under distinct pressure, and two test tubes, or about 40 c.cm., were drawn off before the fluid flowed at normal rate. The removal of this fluid did not result in any clinical improvement. The total cell count numbered 5 per c.mm. and these were mainly lymphocytes. The albumin was 0.025 per cent and the chlorides 0.74 per cent.

Diagnosis

A sequence of the development of the following symptoms in children or in young adults is pathognomonic—

1. Progressive bilateral cerebral blindness.
2. Progressive bilateral deafness.
3. Progressive bilateral ataxy.
4. Progressive spastic paralysis.
5. Progressive mental deterioration.

Differential diagnosis

(1) *Disseminated sclerosis*.—Schilder's disease has been described as 'disseminated sclerosis in childhood' because of the scattered lesions and of the obvious demyelination. But the lesions in Schilder's disease are massive as shown by the symptomatology and by the naked-eye post-mortem appearance whilst the

spread of these lesions clinically from one part of the brain to another is rapid. Moreover the brain is selected and the spinal cord is usually spared. Encephalitis periaxialis affects children mainly, and its symptomatology is pathognomonic and distinctive from that of disseminated sclerosis.

Diagram showing the areas of massive macroscopic gelatinization and microscopic demyelination in the white centres of the cerebral hemispheres, which in the case quoted started (1) symmetrically in both frontal centres (with the production of amentia) and (2) symmetrically in both temporal centres (with the production of bilateral deafness), and progressing to (3) both occipital centres (with the production of bilateral cerebral blindness), (4) whilst it spread after a month to both parietal centres (with the production of bilateral ataxy) and (5) to central area (with the production of bilateral spasticity of lower limbs). A more frequent manner of spread through the white centres is from the occipital lobes forward. The surface and section of the cortical grey matter is normal.

(2) *Hyperkinetic type of encephalitis lethargica* is also characterized by spontaneous involuntary movements, restlessness, and mental symptoms. The absence of ophthalmoplegias in Schilder's disease and the presence of the pathognomonic signs is important in differentiating the two conditions.

(3) *Intracranial tumour* may be simulated when headache, vomiting, papilloedema, and perhaps fits, are present, but the absence of optic neuritis with the presence of severe loss of vision and with the signs of an extensive rapidly-spreading disease of the cerebral hemispheres point to Schilder's disease.

AN UNUSUAL CASE OF JAUNDICE ASSOCIATED WITH HODGKIN'S DISEASE

By G. T. BURKE, M.D., F.R.C.P. (Lond.)

LIEUTENANT-COLONEL, I.M.S.

Department of Medicine

and

M. A. HAMID, M.D. (Luck.), M.R.C.P. (Lond.)

Department of Pathology, King George's Medical College, Lucknow University

K. A., Mohammedan male, aged 30, admitted to hospital 19th November, 1934, with fever, general pains, cough and jaundice.

There was no past history of any significance.

Present illness.—Some twenty-five days previously he experienced a chill, followed by fever and cough

with expectoration and general body pain. About fourteen days ago he noticed jaundice and dark coloration of his urine, succeeded by epigastric pain and constipation.

Condition on admission.—Well made and nutrition good. Appetite good. Deep icteric colour; temperature 101°F., pulse normal, no respiratory symptoms.

Abdomen: upper part full; epigastric tenderness; liver enlarged, tender, smooth, and firm, extending from the fourth intercostal space to three finger-breadths below the costal margin.

Spleen: enlarged, smooth, and firm like an old malarial spleen, and extending four finger-breadths below the costal margin though patient said he had only noticed it recently. No ascites and no palpable abdominal glands.

Chest: no cardiovascular abnormality. Lungs normal except for signs of congestion at the right base. Sputum scanty and mucopurulent, with, on the second day, a small piece of rusty brown material, which showed many pneumococci.

Urine: dark, containing bile salts and pigment.

Stools: clay-coloured at first, but after saline purgative showing some bile; no parasitic infection.

Blood: Van den Bergh's reaction, immediate, direct, strongly positive, total white count, 1,600 only, with 80 per cent polymorphonuclears and 20 per cent lymphocytes. This was repeated the next day with result, 1,760, 76 per cent polymorphonuclears and 24 per cent lymphocytes.

22nd November. Wassermann reaction of blood, strongly positive.

23rd November. Tests for kala-azar, negative.

24th November. Total erythrocytes, 3,500,000; haemoglobin 60 per cent, white count 2,400, with 70 per cent polymorphonuclears, 28 per cent lymphocytes, and 2 per cent eosinophils.

Progress.—Fever remained at 100°F. to 101°F. daily, but patient's general condition was good; four daily injections of one grain of emetine hydrochloride were given with no effect on the temperature or on the size or tenderness of the liver. His main complaint was that he was not given enough food. Jaundice remained unchanged, with light bile-coloration of the stools.

In the night of 25th November, 1934, he complained of vague discomfort, but did not look worse. About daybreak on the 26th he suddenly got out of bed and, before the nurse could reach him, fell in a fit, and expired almost before the house physician could arrive.

No post-mortem examination could be obtained, except that the liver was taken out, and an interesting condition was found.

Liver enlarged; weight 4 pounds. Greenish colour; on cutting, bile stained, with dilated portal veins; microscopically nutmeg condition with scattered bile pigment: liver cells around portal canal almost disappeared. Some proliferation of bile ducts and some pericholangitis. An infiltration around the portal canal and between the adjacent cells, consisting of lymphocytes and a few enlarged endothelial cells, some of the latter being multi-nucleated. At places there were isolated collections of such cells in the liver substance. The appearance was that of early Hodgkin's disease of the liver.

At the neck of the gall-bladder was an enlarged lymph gland which, on cutting, showed no necrosis nor degeneration, and microscopically was found to be a typical Hodgkin's gland without much fibrosis.

Comment.—The patient undoubtedly suffered from Hodgkin's disease, though there were no demonstrable enlarged glands during life. The diagnosis during life remained obscure, with syphilis as the most probable cause of the jaundice. The extreme leucopenia was not explained. In view of such an incomplete

post-mortem examination the presumption is that he had abdominal Hodgkin's disease, with some metastasis near the common bile duct giving rise to obstructive jaundice. The necrosis of the liver cells could be explained by the obstruction of the bile flow and the infiltration found in Hodgkin's disease.

FŒTUS PAPYRACEUS

By E. PATTON

Lady Apothecary, Female Dispensary and Maternity Hospital, Davangere, Mysore State

A MULTIPARA VI, with a history of the first four births normal and the fifth an abortion, was admitted

into hospital on the 17th of April. She was said to be full term and was having slight pains.

Examination revealed a full-term uterus and the child was presenting in the left anterior sacral position.

The patient was delivered about two and a half days later of a healthy female child weighing four and three-quarter pounds.

About three-quarters of the placenta appeared normal but the remainder was hard and pale. Two soft masses were found imbedded on the amniotic surface of the membranes. These were opened and each was found to contain a foetus corresponding in size to a three and a half months' pregnancy with the umbilical cords attached to the hard portion of the placenta.

Pregnancy was normal except for slight hæmorrhage lasting three days during the seventh month and an attack of malaria in the eighth month.

I wish to thank Dr. S. Subha Roe for permission to publish these notes.

A CASE OF PELLAGRA

By S. N. GUPTA, M.B., B.S.

House Physician, East Medical Ward, Mayo Hospital Lahore

HIRA DEVI, aged 20, Hindu female, an orphan of the Hindu Orphanage, Rani Road, Lahore, was admitted on the 25th April, 1934, to the Female medical ward of the Mayo Hospital, Lahore, with the provisional diagnosis 'Pigmentation'.

History.—Her parents died when she was only two years old, and she was brought up by a woman friend of the family. She had been living with that woman at Rawalpindi till one and a half years ago when she was sent to the Rani Road orphanage for education. She says she has never lived on maize, her chief diet being wheat, fruits, vegetables, and a sufficient amount of ghee. She gave a history of attacks of unconsciousness (most probably hysterical), which started when she was sixteen years old, but she has had no such attacks for the last six months.

The present complaint started some eight months ago. The first thing she felt was weakness and loss of colour: menstruation became scanty, and ultimately stopped altogether six months ago.

The next complaint was pigmentation; it appeared first on the dorsum of the hands and then gradually spread. She says that the colour was not lighter or reddish brown at first but that it was dark from the very beginning. There was no itching or pain over the pigmented areas.

The diarrhoea started about a fortnight after the pigmentation. It was of a non-fatty type with colicky pain occurring at all hours and was a persistent symptom.

Weakness has gradually increased and with it oedema of the feet has appeared.

She had tried treatment of various ayurvedic and allopathic physicians, but the symptoms had persisted in spite of all this. The patient could not tell much of her past history.

PHYSICAL EXAMINATION

General.—The patient is well developed, not much wasted, but very anæmic. While in the ward, she ran an irregular intermittent pyrexia, the highest temperature being 101°F. As has been mentioned before, there was oedema of the feet and ankles.

Alimentary system.—Subjective symptoms:—Appetite is very poor, no vomiting, no eructations nor flatulence. Bowels open six to seven times during the twenty-four hours, fluid stools, no blood nor slime, no tenesmus, the stools are not fatty. Colicky pains complained of all over abdomen. No jaundice, no piles, no hæmatemesis.

Physical examination :—

Teeth .. normal;
Gums .. very pale;
Tongue .. dark pigmentation over edges and tip, at other places very pale, flabby, movements normal;
Stomach .. nothing abnormal detected on palpation and percussion; fractional test meal examination showed complete lack of free hydrochloric acid and a low total acidity;
Intestines .. examination of faeces showed no amœbæ, cysts or ova; the cellular content was low, liver and gall-bladder normal, spleen slightly enlarged.

Circulatory system.—Subjective symptoms :—Dyspnoea and palpitation on slight exertion, œdema of the feet, no precordial pain or distress.

Pulse rate 98 per minute, regular, vessel walls not thickened, volume small, force and tension normal, no abnormality as regards rise, maintenance and fall of pressure.

Examination of precordia.—Inspection :—Apex beat visible in the fifth space, just a shade outside the mid-clavicular line; no pulsation seen in epigastrium or neck.

Percussion :—

Upper border—at the level of second intercostal space.

Right border—just at the lateral border of sternum.

Left border—a little external to the mid-clavicular line.

Auscultation.—No abnormality in the intensity or spacing of the heart beat. A soft systolic murmur localized in the pulmonary area. A well-marked bruit-de-diabie present over right jugular vein.

Blood pressure was 115 to 80 mm. of mercury.

Blood.—Total white blood corpuscles 6,000 per c.mm. with different varieties of cells in normal proportions.

Total red blood corpuscles 1,250,000 per c.mm.

Hæmoglobin—25 per cent.

Colour index—1/1.

Poikilocytes present, but no nucleated red corpuscles were found, no anisocytosis.

Respiratory system.—Subjective phenomena :—Slight dry cough, no expectoration, no pain in chest, dyspnoea only on exertion.

Physical examination of chest :—No abnormality detected.

Urinary organs.—Normal. The urine report shows no abnormality except the presence of albumin in traces.

Skin.—Dark pigmentation over dorsum of hands and feet extending to the distal third of forearms and legs, backs of elbow joints, bridge of nose and adjoining portions of cheeks, and back of neck. Distribution of pigmentation is bilateral and symmetrical. In the pigmented areas, skin is dry and thickened.

Nervous system.—Intellectual functions :—The patient is always depressed and irritable, does not like to talk, otherwise no abnormality.

No other abnormality in other nervous functions.

Wassermann reaction.—Negative.

Diagnosis.—The condition was diagnosed as pellagra by the visiting physician on the following grounds :—

- The typical skin lesions with their symmetrical distribution over the exposed parts of the body,
- the non-fatty type of persistent diarrhoea,
- presence of mental irritability and depression,
- irregular pyrexia, and
- history of living in an orphanage.

The rarity of the disease in this part was against this diagnosis, but no other disease would give a similar clinical picture. The diagnosis was subsequently clinched by the 'therapeutic' test.

Treatment.—She was given symptomatic treatment for her diarrhoea, sodium bicarbonate colonic wash and a soda bismuth chalk mixture. Iron and arsenic were also given to improve the anæmia. But the most important item in her treatment was the supply of vitamin B; she was given marmite one teaspoonful thrice daily and improved steadily. A month after admission to the ward the diarrhoea had stopped, appetite was much better, and pyrexia had disappeared. Pigmentation over nose and face disappeared, only slight traces left on the dorsum of hands; pigmentation over dorsum of feet not much improved as yet. Œdema of feet is just the same; anæmia is also not much improved, the blood count being :—

Total red cells = 1,750,000.

Hæmoglobin = 40 per cent.

After the 20th May she was put on liver in addition. This was given in the form of Campolon (Bayer) 2 ccm. intramuscularly every third day. This improved both the general condition and the anæmia very quickly and steadily. On the 20th July, 1934, when she was discharged as cured, she had no trace of pigmentation left, and the blood report was as follows :—

Total red cells = 4,500,000.

Hæmoglobin = 90 per cent.

It will be evident from the above that, though all other symptoms improved with marmite, liver treatment was essential for the anæmia.

My thanks are due to Khan Sahib Dr. Yar Mohammed Khan, M.P., for his kind permission to report the case and the valuable corrections and suggestions he has made; to Miss Binapani Dei, student in charge of the case, for the help I obtained from her history and progress report; and to my colleagues Dr. Hamid Hassan and Dr. C. L. Kapur for their valuable help.

A CASE OF CALCULUS FORMATION IN THE PREPUTIAL SAC

By V. N. TRIPATHI, L.M.P. (Agra)

Medical Officer, Civil Dispensary, Sheopur, Gwalior State

GANPAT, a Hindu male aged 45 years, was admitted to the Civil Dispensary, Sheopur, on the 18th February, 1934, for retention of urine. On cursory examination he was found with congenital phimosis with a pin-point central opening through the prepuce. On manipulation the glans penis appeared rather hard which led me to think that the prepuce must be firmly adherent to it. No probe or director could be inserted through the aperture, so the foreskin was divided in the middle with a pair of scissors. After division of the foreskin, I noticed three rather large, smooth and disc-like calculi about the size and shape of a nux vomica seed, evenly formed and centrally arranged one against the surface of the other anterior to the meatus.

The glans penis was rather small and subnormally developed—the prepuce being partially adherent to it—and the meatus was about the size of a big needle's eye. The size of the calculi was much larger than could pass through a normal human urethra, so it seems that they must have formed in the preputial sac from constant locking in of urine there with consequent decomposition and precipitation of phosphates and other salts.

It is remarkable that the patient could go on with constant partial retention of urine accompanied with irritation for such a long time as 45 years without it giving rise to any other grave symptoms.

AN UNUSUALLY LARGE HORN GROWTH

By J. M. RICHARDSON, M.D.

Civil Surgeon, Bilaspur, Central Provinces

I SEND herewith a photograph of a man who came for treatment to the Main Hospital, Bilaspur, recently, from the interior of the district with a large horn growing from the top of his head.

He was a young man of about eighteen years of age. His story was that he had a soft tumour about ten years back which, in the next six years or so, increased in size and then suddenly ulcerated. From this broken skin a horny growth protruded and attained to its present size in about six to eight years, its maximum rate of growth being in the last year. It gave him no trouble and he sought surgical interference only because he could not get any of his village maidens to marry him.

The horn is hard, devoid of any sheath and is of the following measurements :

Five inches in length from base to tip along its convexity.

Two and a half inches in length from base to tip along its concavity.

Four and a half inches in circumference at the base.

Three and a half inches in circumference at its middle.

It sprang from the aponeurosis of the occipito-frontalis and was easily removed. The spotted appearance in the photograph is due to the use of an old film.

[Note.—This report is of considerable interest, in the first place on account of the youth of the patient, because such growths are practically always found in old people only. A second unusual character is the large size of the horn. When in such a situation as the present one surgical removal is easy and the best form of treatment, because a large piece of tissue surrounding the base of the growth can be cut away. This is a necessary precaution on account of the

tendency for malignant degeneration to occur later at the site of the horn if it is not thoroughly removed.—
EDITOR, I M G]

A CASE OF TRIPLET PREGNANCY

By K. B. SEN ROY, BSC, MB, BS., P.M.S.

Medical Officer in-charge, Sadar Hospital, Ghazipur

A FEMALE named Swarathia, Ahir by caste, aged 35 years, multipara, of village Garthauli, came to the Dufferin Hospital, Ghazipur, at 2 a.m. on the 30th August, 1934, with one female child born but still attached to the mother by the cord.

This child was delivered at her house in her village at about 7 a.m. on the 29th August, 1934, with very slight labour pains.

In spite of the delivery of a child, the enlargement of the abdomen did not appear to have diminished. The pains were very slight.

On admission the usual routine procedure for normal labour was gone through when the second child, a male, was born at about 4-30 a.m. and the third, also a male, was born at 5 a.m. on the 30th August, 1934. The delivery of both the children was quite normal, the presentation being occipito-anterior. The placenta, which was single, was delivered fifteen minutes after the third child.

All the children were quite healthy. The first female child weighed six pounds and the second and third males weighed six and a half pounds each.

In the accompanying photograph, the female child is lying on the ground whereas the two male children are in the mother's lap.

The mother left the hospital quite well on the fourth day after her delivery.

This case is of interest because it is unusual for triplets to be served by a single placenta, and the size of the children was also exceptionally large.

I am thankful to Dr. Gourinath, L.M.S., Civil Surgeon, Ghazipur, for his kind permission to publish the case and to Dr. (Miss) Lee, Medical Officer-in-charge, Dufferin Hospital, Ghazipur, for furnishing me with notes about the case.

Indian Medical Gazette

MARCH

DRUG ADDICTION IN INDIA

Drug addiction is one of those unfortunate subjects which is nobody's special concern. Those who give the matter any thought usually consider that 'something ought to be done about it', but by somebody else, and they seldom have any very clear idea what this something is and by whom it should be done; the vast majority, however, prefer not to think about it at all and to hope that by this simple expedient they may ensure its non-existence in their own particular world. This way of escape from responsibility is not, however, open to the conscientious medical practitioner.

To the average medical man drug addiction suggests opium, the League of Nations, legislation, the finance department and the excise authorities; his next mental reaction is that it is a dangerous subject with too many social, political and even international implications, and that therefore it had better be left severely alone. Nevertheless, drug addiction is primarily a medical subject. If the smoking of opium were no more harmful than the smoking of tobacco, or if the opium *goli* were as innocuous as chewing-gum or even *pan*, this drug would never have come within the purview of the League of Nations and governments of individual countries could have looked upon it simply as a legitimate and very valuable source of revenue. Unfortunately, the opium habit is a harmful one, both to the body and to the mind, and, therefore, together with other drug habits, it becomes a medical subject of very considerable moment; and on this fact alone does its importance in other spheres depend.

The reasons that can be assigned for the neglect of the drug-addiction problem in general appear to operate with greater force in this country than in most others. The vastness and many-sidedness of the problem are to a great extent responsible for this, but there are additional excuses for this neglect, the first of which is a very familiar one, namely, that there are so many more acute, more dramatic, and, from the point of view of the medical investigator, more promising diseases—and disease it must be considered—than drug addiction; another is that in India there are so few residential institutions of any kind, infirmaries, sanatoria or mental hospitals, where more chronic conditions can be treated and none, as far as we know, devoted to drug addicts. We do not suggest that the time has yet come when the absence of these institutions is a slur on the state of advance of civilization in this country, but nevertheless the investigator

is discouraged by the fact that the forms of treatment most in use in western countries cannot be applied here on account of the absence of the institutions which are an essential part of these treatments.

In view of all these considerations, it is very much to the credit of Colonel Chopra and his co-workers at the Calcutta School of Tropical Medicine that they have taken up this 'unpromising' subject during the last seven or eight years. Their investigations were facilitated by a grant from the Indian Research Fund Association, which has enabled them to carry out these investigations in every part of the country.

The results of this work have been published in a series of articles which have appeared from time to time either in this journal or in the *Indian Journal of Medical Research*, and the paper in this issue summarizes some of the observations of these workers up to the present.

This enquiry has thrown considerable light on a subject about which little was hitherto known and has brought to our notice a number of important facts which will be invaluable to those interested in the medical aspects of drug addiction, but, as Colonel Chopra has repeatedly pointed out, he has so far only touched the fringe of a subject on which there is still much important work to be done; the reports that have been issued have already attracted the attention of those concerned with drugs of addiction in their social, commercial, financial and international aspects.

One point is brought out very clearly, namely, that drug addiction is not static; everywhere there are signs of the older drugs losing their grip on communities as a whole, and their popularity amongst the younger members in particular; in some communities that forty years ago were notorious for their addiction to opium, there are now far fewer addicts and the average consumption of opium per addict has fallen to more than half its previous figure.

That is the bright side of the picture, but there is another side; new addictions are establishing themselves and in most cases these addictions are more insidious and more detrimental to the addict. The drugs used are not only the alkaloids such as morphia and cocaine, which are subject to official control, though they are still smuggled into India from the Far East in large quantities, and in some towns in India are becoming a very serious problem, but other drugs such as chloral hydrate and the barbiturates over which there is no control and which can be purchased over the counter by anybody. There is no provision in the Poisons Act of 1920 (amended 1931) for these and other potential drugs of addiction, and there is here an excellent opportunity for intelligent legislation to step in and prevent these drugs becoming drugs of addiction before they have

established themselves. In the Poisons and Pharmacy Act, 1908 (amended 1926), of Great Britain such substances are placed in part II of the schedule, which means that they can only be sold on the prescription of a qualified medical man; such a provision does not impose any great hardship and if the Poisons Act were amended on these lines it would do much to control the sale of these drugs.

The consumption of hemp drugs has decreased considerably during the last few decades, but it is estimated that there are still over a million addicts, and there is considerable evidence pointing to the association of hemp-drug addiction, and insanity and crime. This in itself presents a problem which promises to repay more thorough investigation.

Just as is the case with most other medical problems, the drug-addiction problem in India presents many special features. In Europe and America drug addiction is usually much more acute; the addict uses the purified alkaloids in most instances and either kills himself within a few years, or goes into an institution and becomes cured. In India it is quite different, drug addiction often—one might say usually—takes on a much less acute form, and it is not uncommon for addicts to remain addicts for twenty, thirty, and even forty years; little is known about the pathological changes that occur in these chronic addicts, as there has been no scientific investigation of the effects of prolonged administration of these drugs.

Treatment of drug addiction is another important problem; it is fraught with many

difficulties, not the least amongst these being that the patient himself usually has little real wish to be cured, and therefore it is essential that the physician should be able to exercise some personal psychical control over the patient; this is all the more essential where institutional treatment is not possible, but there are certain drugs which can be given that will help the addict during the period of withdrawal and which in themselves present less difficulty when the time comes for their withdrawal. An interesting method, which has been introduced comparatively recently, consists in the subcutaneous injection of vesicatory fluid obtained from the addict himself; very remarkable results have been claimed from this and it has the great advantage of extreme simplicity.

From the economic point of view the loss to the country through drug addiction can well be imagined, when it is calculated that there are 3 to 4 million adult addicts in British India alone and in many of the Indian states things are said to be much worse; without considering the possibility of these people being a charge on the community by becoming insane or criminal, they present a considerable loss as they nearly all cease to be of any economic value to the community from the time that they become addicts.

But as we have already said this problem of drug addiction is primarily a medical one and we hope that Colonel Chopra's work will stimulate an interest in a subject which up to the present the medical profession in this country has tended to neglect.

Commentaries

DISTRIBUTION OF SIMPLE GOITRE IN DERBYSHIRE

BEFORE the Royal Society of Medicine in the section of Epidemiology and State Medicine, on 28th April, 1933, Dr. P. H. J. Turton presented the results of his many years' work on the distribution of simple goitre in Derbyshire, which is of profound interest to those in contact with endemic goitre, and especially to those who have hesitated to discard the old view that endemic goitre in certain areas is mainly due to an excess of calcium and to accept, without reserve, the modern view that such goitre is really due to iodine deficiency.

So great an influence have the results of laboratory animal experiments, chemical analyses, and deficiency theories obtained with the medical profession that the value of the great experiments of nature in the super-endemic areas of goitre are in danger of being overlooked. Such laboratory work is of great value and has provided a new angle of vision to the problem of goitre. Moreover field

investigations in some instances appear to support an iodine deficiency theory. But just as laboratory results in a clinical case must be tempered by the wise discretion of the investigating physician, so laboratory results in relation to endemic goitre must be valued by field workers in super-endemic regions such as in the Himalayas, where the goitre rate frequently rises to 50 per cent, and maybe to 80 per cent of the population of the area affected. The pendulum has swung too far in the direction of iodine deficiency as the sole or even primary factor responsible for endemic goitre. To sponsor any other cause of goitre has become almost a heresy in modern medicine, to such an extent that even a standard textbook of medicine, such as Price's, has now no reference to calcium as even a factor in goitre production.

The remarkable connection between goitre and calcium in water in those super-endemic areas, the Himalayan and sub-Himalayan regions of the United Provinces, has already been described (Stott, *Indian Journal of*

Medical Research, April 1931). The conclusion has been reached that the most probable cause of endemic colloid goitre of the United Provinces is an excessive intake of calcium through the drinking water. There was no evidence that iodine deficiency nor intestinal infection from polluted water supplies were the primary cause of goitre in the United Provinces.

The diets of almost all villagers in the endemic area were undoubtedly markedly deficient and the waters of all wells were undoubtedly markedly polluted, but no such clear relationship existed between such deficient diets and such polluted wells and the endemic and non-endemic villages (which often adjoined), as was shown to exist between calcium water supplies and goitre villages (Stott, *Indian Journal of Medical Research*, July 1932).

Dr. Turton's able, full and painstaking investigation on the distribution of goitre in Derbyshire adds fresh interest to the subject. Dr. Turton spent a large part of eight years (1923 to 1930) in his survey. He examined 40,044 children between 8 and 13 attending the Derbyshire elementary schools and found that the goitre rates varied according to age between 1 and 10 per cent for girls and 0.5 and 4 per cent for boys. The average for school children varied between 2 per cent and 8 per cent, according to locality, for small goitre, and between 1 per cent and 2 per cent for goitres sufficiently large to cause a bulging or superficial inspection. No cretins, congenital deaf-mutes, or adults with myxoedema were recorded. The degree of endemicity therefore was hardly comparable with the super-endemic Himalayan areas.

Geology.—The whole of Derbyshire is based on mountain limestone, and areas with a water supply from carboniferous limestone have always been goitrous, but a number of places have been supplied with water from millstone grit of sandstone with the result that the disease has either disappeared or greatly diminished. The incidence of goitre in the millstone grit (sandstone) areas, as compared with the limestone areas, is about 4 to 1 in favour of the limestone.

Influence of iodine content of soils and water.

—From an analysis of the iodine content of many soil and water samples, Dr. Turton shows that the results obtained indicate that there is no definite correlation between the iodine content of drinking water and the goitre incidence in Derbyshire, and again that so far as he has been able to go there is no evidence that iodine insufficiency is or has been a principal factor in the genesis of goitre in Derbyshire.

Orr and Taylor independently have concluded that at present no correlation between the level of iodine in drinking water in England and the

incidence of endemic goitre has been made out.

In Heanor, each child was given 1/10 grain iodine in sweets, weekly, and the public water supply was iodized by the addition of sodium iodide in such an amount that, if a person consumed four pints of water a day, he would receive in one year 14.9 mgm. of sodium iodide. No decrease in the incidence of thyroid enlargement was observed in ten to eleven months in any series receiving either iodized water alone, or iodized water *plus* sweets. From this experiment Dr. Turton concluded, whatever the cause of goitre in these children, iodine deficiency was not the sole cause.

Dr. Turton does not regard these goitres entirely as colloid goitre, but remarks that even with goitre there is no deficiency of iodine in the gland, in which it seems to be 'locked up'. Excess of calcium is, he says, certainly involved in the production of colloid goitre, which is the only type of simple goitre amendable to iodine therapy.

The influence of water supply.—'There is a good deal of evidence in Derbyshire that drinking water is a powerful agency in the production of goitre. Goitre has either diminished or disappeared in many places following the introduction of better water supplies. Where two water supplies exist, it is common to find that one is goitre-free and the other is associated with goitre. Since the water of Heanor has been efficiently filtered and continuously chlorinated there has been a marked reduction in the goitre incidence. If there was any exciting cause for goitre at Heanor it was not iodine deficiency'.

In regard to calcareous water, whether the chalk was in suspension or in solution, causing goitre, Sir James Berny during his goitre observation in Derbyshire observed that in many goitrous localities calcareous matter in very fine division was in the water supplies. When goitre was common in Heanor there was certainly a great deal of suspended calcareous matter in the treated water. The reduction in the goitre incidence followed the removal not only of calcareous suspended matter but also of noxious animal matter. There is no doubt that calcium excess does play some part in the production of colloid goitre, but it appears that unbalance of calcium and phosphorus, or unbalance between calcium phosphorus and iodine, is responsible. Dr. Turton produced a colloid goitre in a male dog, sixteen days after giving it sterilized calcareous deposit from the sedimentation tanks of the Heanor water works.

Influence of ill-balanced diets.—The chief fault in the diets of goitrous Derbyshire children are often a total absence of fresh vegetables and fruits, the substitution of butter by margarine, too much reliance on white bread, and insufficient meat and milk. An improperly balanced diet is a much more important factor

in the genesis of thyroid disease than was formerly supposed. Not only is thyroid disease related to vitamin unbalance or deficiency but also to mineral unbalance between calcium phosphorus and iodine. To consider diet from the view-point of iodine deficiency alone is much too narrow and leads only to the greatest confusion.

Conclusion

Dr. Turton concludes that the cause of goitre in Derbyshire is not any single agent. Impure and unprotected water supplies, and intestinal infection, possibly specific, play a large part and have played a large part in the production of goitre. But there are so many variations within the same region of supply that certainly there are other factors in operation apart from

puberty or sex. Food supply in relation to mineral unbalance, iodine deficiency or vitamin content all no doubt play their part. Simple goitre is a misnomer: the problem of causation is by no means simple.

Dr. Turton states that he has indicated the distribution of childhood goitre in Derbyshire, and leaves it to others to solve the problem of the very definite relationship between goitre in the limestone region of Derbyshire and the almost total absence of the disease in the sandstone region in the south.

THE DEVELOPMENT OF OPHTHALMOLOGY IN BENGAL*

By E. O'G. KIRWAN, F.R.C.S.I.
LIEUTENANT-COLONEL, I.M.S.

*Professor of Ophthalmology, Medical College
Hospitals, Calcutta*

DURING the régime of the East India Company the first properly organized hospital, the Calcutta General Hospital, was established in 1790 in Calcutta. This was followed in 1792 by the opening of the Calcutta Native Hospital. The former is now represented by the present Presidency General Hospital, the latter was rebuilt and renamed as the present Mayo Hospital which was opened in 1874.

The Calcutta Native Hospital appears to have been the first institution to provide scientific treatment for diseases of the eye, and, even now, in spite of more up-to-date hospitals in Calcutta, the Mayo Hospital still carries the tradition among the inhabitants of Bengal as a place from which blind persons return with their sight restored.

Centuries before the introduction of the European system of medicine into India, the treatment of eye diseases was in the hands of quacks and couchers, better known as *mals*, *rawals*, or *hakims*. Cataract and eye diseases being very prevalent in India, these quacks abounded everywhere. Some of them attained a considerable amount of skill and established reputations for the cure of cataract.

Old records are available which relate that officials, business men and planters suffering from eye diseases were apt to consult established *mals* and, even when European medical

treatment was available, a *mal* named Sham Charan flourished in Bengal in the early days of the East India Company, and his name can be traced in the official records.

It was easy for the successful *mal* to score over the European surgeon in those days, and no wonder, as the former would travel from one end of the country to the other with his instruments and paraphernalia, leaving in his trail a certain amount of success and happiness, though more often failures and sufferings produced by his handiwork, which were attributed to the work of evil spirits or bad luck.

In the year 1798, Dr. Shoolbred, the superintendent of the Calcutta Native Hospital, published in the annual transactions of the hospital the treatment of two cases of cataract, 20 cases of phlegmon of the eye, and 30 cases of ophthalmia. The number of eye cases reported in the hospital transactions treated in this institution steadily increased from year to year.

In the year 1816, Dr. Luxmore, an assistant surgeon in Calcutta, petitioned the Governor-General in Council for an endowment to extend and improve his private eye hospital which was situated in Chowringhee, and which was apparently opened two or three years previously. In his application he states, 'The various opportunities I have had in the treatment of cataract have afforded me the pleasing gratification of rendering the operation so successful as generally to restore sight to those who were blind from any species of cataract, from the infant born in that state to the adult at an advanced period of life provided there was no other defect in the organ of sight'. His petition was forwarded to the Medical Board and Doctor R. Leny, secretary of the Medical Board, replied that 'Many eye cases are at

*A paper written for the centenary of the Calcutta Medical College in January 1935.

present cured in the Calcutta Native Hospital in which the operation for the cure of cataract is performed with great skill and success and where professional assistance for these kinds of cases is never refused. The Government by granting an additional pecuniary aid to the Native Hospital would enable the governors of that institution to construct an exclusive ward for diseases of the eye'. Since that date the Calcutta Native Hospital kept a separate register of eye diseases although no separate ophthalmic department was opened.

In the year 1828, the Hon'ble Directors of the East India Company in London sent Doctor C. C. Egerton to Calcutta to establish an eye hospital there. He is mentioned as having been trained in ophthalmology in London under Dr. Travers who was the leading eye doctor in England at that time.

The Eye Hospital situated at the junction of Wood Street and Theatre Road, Calcutta, on the present site of the Saturday Club and mentioned in old records, was probably started by him.

From the years 1800 to 1850 mention is made in official records of the following surgeons who carried out treatment of diseases of the eye:—

Dr. J. Shoolbred	..	1794-1821
" P. Breton	..	1801-1830
" J. Jameson	..	1807-1820
" T. Luxmore	..	1813-1825
" Simon Nicholson	..	1816-1855
" J. R. Martin	..	1817-1839
" C. C. Egerton	..	1824-1847
" E. W. W. Raleigh	..	1839-1845
" R. O'Shaughnessy	..	1841-1845
" J. Jackson	..	1845-1855

Dr. Peter Breton was superintendent of the first Native Medical School in Calcutta. He was a very versatile author, and among his writings was an article on the native method of couching, published in 1826. He died in Calcutta in 1830.

Dr. James Jameson was the first superintendent of the Calcutta Native Medical School in 1822. He died in Calcutta in 1823.

Dr. Thomas Luxmore died in Lucknow in 1828.

Dr. Simon Nicholson was one of the original fellows of the Royal College of Surgeons of England and died in Calcutta in 1855, having given 48 years' service. His picture in oils is in the rooms of the Asiatic Society, Calcutta.

Dr. James Ronald Martin was the surgeon superintendent of the Calcutta Native Hospital from 1830 to 1839. He was one of the original fellows of the Royal College of Surgeons in 1844 and was the first president of the Medical Board of the India Office in 1864. He was made a fellow of the Royal Society in 1885 and was knighted in 1860, and was a writer of repute.

Dr. C. C. Egerton was also one of the original

fellows of the Royal College of Surgeons of England.

Dr. E. W. W. Raleigh was an original fellow of the Royal College of Surgeons.

Dr. John Jackson was an original fellow of the Royal College of Surgeons of England in 1844 and became a fellow of the Royal College of Physicians of London in 1859. He was an author of repute.

Doctors Breton, Jameson and Nicholson are also mentioned in connection with the teaching of medical students in diseases of the eye.

In the year 1835, the Calcutta Medical College with its associated hospitals was established and in the records of those institutions, the earliest eye work mentioned was in the year 1840, and the name of Doctor Martin is associated with it. He was the first part-time professor of ophthalmology. An actual separate eye department in connection with the Medical College Hospitals was established in the year 1860 in Halliday Street at the site now called Mohomed Ali Park, south of the present Fire Brigade and Ambulance Station on Chittaranjan Avenue. Dr. Archer was the first surgeon in charge and in addition was also part-time professor of ophthalmology in the Calcutta Medical College. He introduced more modern ophthalmic methods in diagnosis and treatment. He adopted the extraction operation for the cure of cataract, the iridectomy operation for glaucoma, condemned the operation of couching as practised by *mals* and *kabirajis*, and introduced the ophthalmoscopic examination of the eye with Libreich's ophthalmoscope. Many other improvements, including the regular use of chloroform anaesthesia in intra-ocular operations, are attributed to him.

In 1867, Dr. Archer was succeeded by Major N. C. MacNamara, I.M.S., who later made for himself a great reputation as an able ophthalmic surgeon and teacher as well as a great administrator. It was due largely to his initiative and energy that the present Mayo Hospital was built and opened in 1874. He was the first professor of ophthalmology in the Calcutta Medical College. He was a pupil of Sir William Bowman, F.R.S., and studied under many of the leading ophthalmic surgeons in Europe at that time, and verily can be classed as the father of modern ophthalmic teaching in Bengal. It is now of interest to know that he disagreed with the theory then prevalent that the lens was composed of tubular fibres and cataract was due to molecular changes taking place in the lens. He taught his students that cataract in very many cases was due to fatty degeneration of the lens fibres and this condition may be induced by causes affecting its nutrition whether arising from alteration in the blood, from defective innervation, mechanical separation or, lastly, inherent defects in the germinal matters from which the fibres of the lens are formed. He advocated

and practised the removal of the cataractous lens by linear extraction with a horn scoop without iridectomy for all forms of cataract affecting the inhabitants of India, whether European or Indian. He forcefully condemned the operation of reclinatio which was at that time discarded by the majority of surgeons in Europe, but nevertheless still had its advocates, as well as being the method of adoption by the *kabirajis* and *muls* in India. He advocated removal of the lens in its capsule in cases of immature cataract that had caused considerable impairment of vision so that none of the soft and transparent cortical matter might attach itself to the iris.

In 1867, the year that MacNamara became the first whole-time professor of ophthalmology, the senate of the Calcutta University insisted on students coming up for examination not only producing certificates of having attended an ophthalmic hospital and lectures on the subject, but that each should pass a clinical as well as a written examination so that the test entailed a practical acquaintance with the principles of ophthalmology.

In MacNamara's time cocaine had not come into use in ophthalmic surgery, the operations being done without an anæsthetic or under chloroform. He was a great advocate of doing all eye operations under chloroform and disagreed with Von Graefe who did not approve of chloroform. Ether anæsthesia was then thought to be impracticable in warm climates. He described the technique to prevent vomiting after operation which was the great argument put forward against chloroform.

Dacryocystitis and mucocele, which are very common diseases in Bengal, were at that time treated palliatively by the use of probes and more radically by destruction of the lacrimal sac by chemicals which were followed later in some cases by the removal of the lacrimal gland.

In 1874, MacNamara retired to practise in London, where he quickly became a prominent ophthalmologist, was appointed to the staff of the Westminster Ophthalmic Hospital and later became vice-president of the Royal College of Surgeons of England.

In 1867, he published an excellent textbook on ophthalmology, based on the lectures he delivered to the students of the Medical College. His work was subsequently translated into Hindi by his able assistant Dr. Lal Madhab Chatterjee.

Major Caley, I.M.S., succeeded MacNamara and it was in his time as professor of ophthalmology that the Halliday Street Eye Hospital with its 20 beds was abolished, and its equipment, apparatus, etc., transferred to a portion of the Medical College Hospitals in the building in which the present emergency and observation wards are located.

Major Caley was succeeded in 1886 by Major R. C. Sanders, I.M.S., and from this year to the early years of the present century, Sanders dominated the ophthalmic world in Bengal and was the most prominent ophthalmic surgeon since MacNamara. He was a very skilful surgeon and built up an extensive private practice. He is still remembered widely by many of the older residents of Bengal, some of whom owe their eyesight to his handiwork. He was not, however, a good teacher. In his time, in the year 1891, the Shama Charan Law Eye Infirmary was opened with 57 beds at the junction of Colootollah and College Streets; this was due to the munificence of Babu Shama Charan Law. The Medical College Eye Department was shifted to this hospital from this year.

In 1901, Sanders retired from the professorship of ophthalmology, but continued to reside and practise in Calcutta. The Marwari population in Calcutta built the present Marwari Hospital on Harrison Road in the year 1902, and he was the first surgeon in charge and popularized that institution as a centre for the treatment of eye diseases.

In 1901, Lieut.-Col. J. Lewtas, I.M.S., succeeded Sanders as professor of ophthalmology and remained for four years. Lewtas is still remembered as a very pious man who prayed in the Board Room of the Mayo Hospital before starting the work of the day.

In 1905, he was succeeded by Major Maynard, I.M.S., who was later to follow in the footsteps of MacNamara and Sanders in making a great reputation both in and out of India and, with other distinguished ophthalmologists of his time in India, Lieut.-Cols. Elliot, Herbert and Smith, add renown to Indian ophthalmology.

In 1910, Maynard pointed out the necessity of a new, enlarged and modern eye hospital and school which would be worthy of such a large city as Calcutta. He drew up the plans of the present Eye Infirmary and, due to his enterprise, energy and skill, his proposals were finally approved by Government in 1916. Owing to the Great War and lack of sufficient funds, Maynard was destined not to see the fruits of his labour completed as he retired in 1919 and the new Eye Infirmary was not finished till 1923. It was finally opened for the reception of patients in September 1926 during the period that Major Kirwan, I.M.S., was officiating professor of ophthalmology.

Maynard was a writer of repute, his best work perhaps being his two manuals of ophthalmology published in 1929 and based on the systematic course of lectures he delivered to the students of the Medical College, Calcutta.

In 1919, Major W. V. Coppinger, I.M.S., succeeded Maynard, and during his time ophthalmology entered upon a new phase with the

advent of the Gullstrand slit lamp and corneal microscope. The present Eye Infirmary was equipped with every modern apparatus. The special pathological department of the Eye Infirmary alone lagged behind; this part of ophthalmology continued to be carried out by the department of pathology in the Medical College.

In 1928, two honorary ophthalmic surgeons were appointed to the visiting staff of the Eye Infirmary, Dr. S. K. Mukherjee, F.R.C.S.D., and Dr. T. Ahmed, F.R.C.S.E., and both still remain on the staff.

In 1929, the present professor, Lieut.-Col. E. O'G. Kirwan, I.M.S., succeeded Coppinger, and is still in charge.

During the last five years, ophthalmology has undergone considerable progress and change.

The intracapsular operation for cataract, carried out in Northern India by Lieut.-Col. Smith, I.M.S., and his students and performed according to his technique, was never popular with ophthalmologists working in Calcutta about that time, being condemned as unsafe as a routine method for the extraction of cataract.

The intracapsular operation recognized by most ophthalmologists as the ideal one is now carried out extensively by safer methods such as the Barraquer suction apparatus and by the intracapsular extraction forceps, so much so that fully 50 per cent of all cataracts taken out in the Eye Infirmary in the Medical College in the last year were done by the intracapsular method.

Much progress has been made in the diagnosis and treatment of glaucoma, so common in Bengal.

With the advent of diathermy, the treatment of retinal detachment, formerly a hopeless condition to treat, has taken on a new phase and fully 50 per cent of all cases can now be cured.

Plastic surgery with conjunctival and skin grafts has been developed to a very high degree of efficiency.

Finally, corneal transplantation in cases of opaque corneas has been carried out in the present year with excellent and promising results.

The present Eye Infirmary of the Medical College Hospitals consists of 139 beds in the intern department and a huge out-patient department which is capable of handling up to 400 patients a day for the treatment of eye diseases and refraction errors. Here also is located the office of the Association for the Prevention of Blindness, Bengal.

The work of the Eye Infirmary shows an ever-increasing popularity and an analysis of

the work done in the last six years is shown below :—

Indoor patients				
Year		New	Old	Total
1928	..	2,364	33,875	36,239

1931	..	27,504	58,195	85,699
1932	..	31,890	57,890	89,780
1933	..	33,769	60,784	94,553

The magnificent work carried out by Indian ophthalmologists in the advance and progress of ophthalmology in Bengal must not be overlooked. In the early days in Bengal, they were trained by the European doctors practising eye diseases and had much to contend against in the way of *kabirajis*, *mals* and quacks of all kinds. From the year 1860 onwards the name of Dr. Nil Madhab Halder appears in official records as an eye doctor of repute and his name is still remembered. Later, Dr. Lal Madhab Mukherjee, who was assistant to Lieut.-Col. MacNamara, established a great reputation as a surgeon, teacher and writer. From 1870 onwards, Dr. Khirode Nath Dutt was also a prominent eye doctor practising in Calcutta. He was attached for 45 years to the Mayo Hospital, retired in the year 1927 and died only recently, in 1934, in his 80th year. His brain remained very clear up till the end, and he was present at the Third Conference of the All-India Ophthalmological Congress held in Calcutta in 1933. It was of great interest to hear from him that in the last decade of the 19th century and the first decade of the 20th century that ophthalmic practice consisted more in prescribing remedies than in doing intra-ocular work.

Other prominent Bengali doctors who flourished about the end of the last century were doctors Mon Mohan Bose, Atul Bose and K. K. Bagchi.

In the history of ophthalmology of Bengal, the name of Dr. M. K. Chatterjee must not be overlooked. He was formerly on the staff of the Mayo Hospital for seven years, was the founder of the Eye Department in the Carmichael Medical College, Belgachia, and still remains in charge.

My thanks are due to Captain S. Dutt for his help in searching through the records to obtain information in writing this history.

All over India cataract is a common disease of the eye in elderly people and operations for the cure of cataract are very common. As it

is a speciality that has made ophthalmologists working in India the most expert cataract operators in the world, it is of interest to give a short account of the development of the technique of cataract operations.

In the year 1748 Davel in France and his colleagues in Europe had been advocating the extraction operation for cataract. In Bengal, and in India in general, it can be found from old records that three methods of the cataract operation were in vogue amongst ophthalmologists of those days (1790 to 1858), depression (or reclinatioⁿ or couching), extraction and needling.

Of these, for many years the operation of depression was looked upon as the easiest operation and the one of choice in the hands of surgeons of average skill in the general class of patients met with in practice in India.

The operation of extraction, which undoubtedly led to excellent permanent results if successful, had so many pitfalls and complications in those days that only skilful and experienced

eye surgeons practised it and then only on selected patients. There was no preliminary cleansing of the conjunctival sac and the operation was done either without an anæsthetic or under chloroform. It can therefore be surmised how frequent bad results were. The extraction was carried out with a Beer's knife which was pushed from one end of the cornea to the other and the section then completed. The lens was either removed by pressure or by means of a specially modelled horn spoon or vectis. This was no mean effort of skill and apparently a fair proportion of the patients operated upon had more or less useful sight; that amount of success was considered satisfactory by those concerned. Nowadays modern work demands, and very rightly so, perfect results, namely vision 6/6 with glasses and to be accomplished with little astigmatism and good cosmetic results. This goal has now very nearly been achieved, and, by modern methods, 90 per cent at least of patients operated upon for cataract recover normal vision.

Medical News

HUNTERIAN SOCIETY GOLD MEDAL FOR PRACTITIONERS

The rules governing the award of this medal have recently been altered.

Any registered general practitioner resident within the British Empire is eligible to compete, and the medal, which is of gold, is awarded annually to the writer of the best essay on a subject selected by the Society.

Competitors—men or women—must be engaged in general practice and essays should be sent in by 31st December.

The essay must be unpublished and original, and be based on the candidate's own observation, but it may contain excerpts from the literature on the subject, provided that reference be made to the articles from which they are taken.

A copy of the rules and any further information can be obtained on application to the Honorary Secretary, Mr. Martin Oldershaw, 26, Upper Wimpole Street, London, W.1.

The subject selected for the essay is, for 1935, 'The Conduct of Midwifery in General Practice' and for 1936 'Rheumatoid Arthritis: Its Diagnosis, Treatment, and End-results'.

LIVERPOOL SCHOOL OF TROPICAL MEDICINE

Presentation of Mary Kingsley Medals

ON 6th November, 1934, Mary Kingsley Medals were presented to two honorary recipients and to four scientists who have rendered distinguished service in the field of tropical medicine. Lord Leverhulme entertained the recipients and a number of former medallists at dinner at the University Club, and afterwards held a reception at the School of Tropical Medicine, which was attended by a large and representative gathering.

The medal was struck in commemoration of the work of the late Miss Mary Kingsley in West Africa many years ago and it is presented from time to time in recognition of brilliant scientific work, for the most part in tropical medicine.

In the present instance two of the presentations were honorary, that to Mrs. Middlemass Hunt being in recognition of the work of her husband as honorary Dean to the school for many years, which on his death was followed by an endowment for the purpose of establishing the post of Director of the Sir A. L. Jones laboratory, Sierra Leone, on a secure footing.

Miss A. R. Caton was given the medal partly in recognition of the work of her father, Dr. Richard Caton, on behalf of the school, and partly on account of her own interest in matters of tropical hygiene, she being secretary of the Indian Village Welfare Association.

The four recipients of the medal for valuable work in scientific medicine were Dr. Henry Beeuwkes, Sir George Buchanan, Sir S. Rickard Christophers and Sir Malcolm Watson.

Dr. Beeuwkes has been the director of the Rockefeller Yellow Fever Commission in West Africa which has been responsible for our great advance in knowledge of this disease in the past ten years.

Sir George Buchanan has been very largely responsible for the formation of the Health Organization of the League of Nations which was the coping-stone of a valuable career in public health work in Great Britain.

The work of Sir Rickard Christophers and Sir Malcolm Watson is so well known to our readers that it needs no comment from us.

CONFERENCE FOR MEDICAL OFFICERS IN INDUSTRY OVERSEAS

It has been felt for some time that sufficient opportunity has not been given to medical officers in

industry overseas to exchange views on the various problems peculiar to their particular industries and to the areas where they are practising.

It is proposed to hold at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C. 1, an annual conference, lasting for two days, in order that medical officers in industry on leave from the tropics may be able to meet their colleagues and discuss their problems. The main subject for discussion will be the prevention of disease, e.g., control of malaria and epidemic diseases in the tropics; water supplies; sewage and refuse disposal; housing; the keeping of records; and hygiene generally.

It is considered that the contacts made at the annual conferences will not only be of value to medical officers attending, but will also establish contacts between these medical officers and the staff of the school.

All medical officers practising on plantations, mines, railways, hydro-electric and construction schemes and development companies generally will be welcomed. The conference each year will be held in July, and medical officers who would like to attend are invited to apply to the organizing secretary.

MEDICAL PRESS AND CIRCULAR

THIS journal re-issued in book form in June last the first series of articles it published under the title of *Modern Treatment in General Practice*; this book was reviewed in our November issue. We are now informed that this first edition is exhausted already, but that a second large printing has been made. The book is made up of 56 chapters, each of which is written by a specialist for the general practitioner putting before him authoritatively and concisely the latest methods of diagnosis and treatment. The fact that this book has had to be reprinted so soon is very clear evidence of its usefulness to the general practitioner. Doubtless also its low price of 11s. 6d. post free has also helped. We congratulate our contemporary on the well-deserved success of this book and again commend it most heartily to our readers.

INDIAN MEDICAL COUNCIL

LIEUTENANT-COLONEL C. E. PALMER, officiating Inspector-General of Civil Hospitals, Assam, has been duly nominated by the Government of Assam as a member of the Medical Council of India, *vice* Colonel J. P. Cameron, C.S.I., C.I.E., V.H.S., resigned.

FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE NINTH CONGRESS

THIS congress is normally a triennial event; it was held in Calcutta in 1927, in Bangkok in 1930 and it was to have been held in Nanking in 1933. However, on account of the disturbed state of China and of the fact that Nanking, the new capital of the country, was in a somewhat early stage of reconstruction at that time, it was considered advisable to postpone the congress until 1934; it was held from 3rd to 8th October.

The delegates to the congress were the guests of the National Government of China, by whose invitation the congress was being held at Nanking. The delegates about 400 in number, including at least 150 foreign delegates, were received and the congress was opened by His Excellency Wang Ching-wei, President of the Executive Yuan. The president and council of the congress were then elected, Dr. J. Heng Liu, Director of the National Health Administration and of the Central Field Health Station, being

unanimously elected as president and Professor E. W. Walch of Batavia as secretary.

The number of papers that had to be read necessitated the division of the scientific sessions into different sections. These were extremely well arranged and conducted; in no instances were the discussions guillotined or hurried, nor on the other hand were sessions unduly prolonged. Round-table discussions on cholera and plague were included in the programme and an unofficial one on kala-azar was also held.

Certain resolutions were formulated at the various sessions and discussions and eventually adopted by the whole congress; these were as follows:—

RESOLUTIONS PASSED BY THE F. E. A. T. M. CONGRESS, 1934

Cholera

1. This congress is of opinion that further investigation of "carriers" is desirable and recommends that such investigation be carried out in the countries of the Far East as and when opportunities arise.

2. This congress, having discussed the question of the protection conferred by the anti-cholera vaccine, is of the opinion that further statistically controlled field tests be carried out especially in those countries where such controlled tests have not yet been done.

3. This congress, having discussed the question of the relationship between the cholera vibrio and allied vibrios and their variants, is of the opinion that further study of this problem is desirable and that as far as possible the workers on this subject in different countries should exchange available information in order to correlate the results obtainable by the different methods employed.

4. This congress proposes that further field and statistical work be carried out in order to obtain more exact information than is at present available regarding the epidemic and endemic areas for cholera in the Far East.

Plague

1. At the Eighth Congress held in Bangkok in 1930, a resolution was passed strongly recommending rat-proofing of vessels as a practical means for preventing the spread of bubonic plague, and the value of this method has been amply demonstrated as a means of reducing and keeping the rat population of vessels to a minimum. Therefore be it resolved:

(a) To bring to the attention of all the constituent governments the urgent advisability of adopting practical measures for the rat-proofing of vessels; and

(b) That serious attention be given to the question of how far similar methods could be employed to keep railway systems free from rat infestation.

2. Be it resolved that in addition to rats and their fleas due attention be paid to other rodents and fleas, particularly *Pulex irritans*, capable of spreading infection.

Malaria

This congress, recognizing the pressing need for co-operative investigations in the problems of malaria control, wishes in particular to emphasize and direct attention to the fundamental importance in malarial epidemiology of studying biochemical changes occurring in the breeding places of anopheline mosquitoes.

This congress considers that advances of practical utility in the control of malaria might be made if the data obtained by workers in the countries of the Far East were made comparable.

It is resolved, therefore, that, with the consent of the governments concerned, such investigations conducted in various countries be co-ordinated through the appointment of a joint committee of chemists and malariologists resident in these countries.

It is recommended that this committee should be invited to formulate the general lines upon which biochemical investigations shall proceed, and that they should be asked to report to the director of the League of Nations' Far Eastern Bureau concerning the principles and methods of study which are likely to be most profitable and from time to time concerning the results achieved from their application.

General

1. That in view of the importance of the food-factor in diseases, a section on food problems be added to the programme of the next congress.

2. That a section on sanitary measures with reference to water supplies and sewage, and garbage disposal be added to the programme of the next congress.

The local committee had prepared a full and very enjoyable programme for the delegates, and on the afternoons not devoted to the scientific session and every evening excursions and entertainments, both scientific and otherwise, were arranged. Those who knew Nanking were somewhat apprehensive regarding the arrangements for accommodation, as there are few hotels, and for transport, as it is a city of great distances, the National Health Administration offices where the meetings were held being nearly ten miles from some of the hotels, but the fears turned out to be groundless, as every one was accommodated comfortably and a fleet of cars was placed at the disposal of the delegates, day and night.

Arrangements were made for those of the foreign delegates who could spare the time to visit other places of interest in China; some delegates went up the Yangtze river to Hanchow and the Gorges, others went to Peiping. In Peiping a local committee had arranged a programme which rivalled that in Nanking. A few hours spent in the wonderful Peiping Union Medical College alone provided sufficient justification for the time spent on the journey from India.

The delegates from India were Lieutenant-Colonel A. J. H. Russell (Public Health Commissioner with the Government of India); Lieutenant-Colonel R. E. Wright (Superintendent, Eye Hospital, Madras), Dr. Pundit (King Institute, Guindy), Dr. Alice Pennel (unofficial), and Dr. L. Everard Napier (Calcutta School of Tropical Medicine). Dr. B. Mukerji also of the Calcutta School of Tropical Medicine, temporarily working at the Henry Lester Institute, Shanghai, attended.

From Malaya the delegates were Dr. R. D. Fitz-Gerald (Director, Medical and Health Services, S. S. and F. M. S.), Dr. Nancy Lowther (Mrs. Fitz-Gerald), Dr. C. L. Park (Director, League of Nations' Eastern Bureau, Singapore), Dr. G. V. Allen (Principal, King Edward VII Medical College, Singapore), Professor J. L. Rosedale (Singapore), Dr. R. Lewthwaite (Institute of Medical Research, Kuala Lumpur), Dr. G. A. Ryrie (Sungei Buloh Leper Settlement, F. M. S.), Dr. J. W. Scharff (Senior Health Officer, Penang), Dr. A. L. Hoops (Malacca), and from Hong Kong Dr. A. R. Wellington (Director of Medical and Sanitary Services) and Dr. R. B. Jackson (Malariologist, Hong Kong).

Although it is only such a short time ago that the conference was held, we regret that we have already to report the death of two of the delegates; Dr. Nancy Lowther (Mrs. Fitz-Gerald) died very suddenly from acute cardiac dilatation in January, and Professor Walch (the general secretary) was killed in the Dutch Air Mail disaster in December; both had many friends in India.

The next congress will be held in 1937; both Saigon and Manila have been suggested as the venues, but, as no specific invitations have yet been received from the governments of either French Indo-China or the Philippines, the final decision has been left to a small committee.

THE ALL-INDIA OPHTHALMOLOGICAL CONFERENCE

The fourth All-India Ophthalmological Conference will be held in Madras during the Easter holidays from the 22nd to the 24th April under the presidency of Lieutenant-Colonel R. E. Wright, C.I.E., I.M.S.

The last conference was held in Calcutta in December 1933.

It is expected that ophthalmologists from all parts of India and from other countries will attend, and those visiting India for sight-seeing purposes will be very welcome should they care to attend.

One day has been set apart for a discussion on the nutritional diseases of the eye.

The importance of the All-India Ophthalmological Society need hardly be pointed out in a country in which eye disease is so common. The committee appeal to all members of the society to make every effort to be present at the forthcoming conference.

Current Topics

Recent Advances in the Treatment of Tropical Diseases

By SIR LEONARD ROGERS, K.C.S.I., C.I.E., M.D., F.R.S.
(From the *Practitioner*, Vol. CXXXIII, October 1934, p. 401)

IN no field has the modern science of chemotherapy produced as great therapeutic advances as in tropical medicine, and especially in the cure of wide-spread protozoal diseases; this is largely due to the possibility of testing the numerous compounds made synthetically by the chemists on animals infected with the parasites of malaria in small birds, trypanosomes in rats, etc. Some of those which were found to be effective in such animal infections have proved to have curative value in the corresponding important human diseases. The following is the present position

of some of the advances in this direction in the last decade or so.

MALARIA

The modern treatment of general paralysis of the insane by the artificial production of malaria has enabled carefully controlled experiments of prophylaxis and treatment of malaria to be carried out with important results. Thus the much disputed prophylactic value of quinine has been tested, and it has been shown that the administration of this drug for some days before mosquito infection with malaria does not prevent infection, but if it is continued daily for seven to ten days after the inoculation of the sporozoites into the human subject by infected mosquitoes, the development of clinical malaria is prevented by the curative action of the drug. Malarial fever produced by direct inoculation of infected human blood is more easily cured than that caused

by mosquito infection. Moreover, benign tertian infections tend to die out in some patients with production of immunity after some months of artificial infection with the disease.

Of still greater importance is the establishment of the value of two new synthetic drugs by experimental treatment of bird malaria, confirmed subsequently in the human subject. The first of these is plasmochin or plasmoquine, a quinoline compound which has the remarkable property of destroying the crescents and other mosquito-infecting gametocytes, which quinine itself does not do; it is being used in small doses, such as 0.02 to 0.03 gramme daily in adults and 0.01 in children, in labour forces to remove the infectivity of their blood to the anopheles and so to act as a prophylactic measure in reducing the prevalence of malaria among them. In larger doses the drug is also curative in benign tertian, though not in malignant tertian, but it is too toxic in such doses to be safe except in hospital cases.

The other effective new drug is atabrin, which is non-toxic and active in all forms of malaria in doses totalling 0.3 gramme daily in one or more doses, 8 to 12 full doses being sufficient; relapses appear to be less frequent than after quinine, although the early hopes that they would be eliminated have not been fulfilled. This drug is also preferable to quinine in the treatment of the blackwater fever complication of malaria, and it is tasteless.

TRYPANOSOMIASIS

Equally important are the advances in the treatment of the most deadly scourge of vast areas of tropical Africa, trypanosomiasis going on to the formerly invariably fatal later stage of sleeping sickness. The success in early cases of such arsenical preparations as atoxyl and soamin led to the production synthetically of innumerable arsenical compounds and their trial against human trypanosome infections of rats and other small animals, and thus resulted the discovery of Bayer 205 in 1900, still a secret German preparation, although Fournieu of Paris has revealed the complicated composition of his preparation 309, which appears to have the same physical and therapeutic properties. Shortly after this Louise Pearce and W. H. Brown, of the Rockefeller Foundation, New York, discovered a still more effective preparation in trypanamide, which has powerful curative action in all stages of the disease, including the late sleeping sickness one, whereas Bayer 205 is active only in the early stages of blood infection before the invasion of the cerebro-spinal system takes place. Both drugs cause rapid disappearance of very numerous trypanosomes from the blood of infected animals and of human subjects, although Bayer 205 appears to be the more effective in the first stage of the infection, and it is also of value as a prophylactic in those much exposed to infection. In early cases four to five weekly 1-gramme doses cure most cases. In the stages with cerebro-spinal involvement Bayer 205 fails to reach all the trypanosomes and trypanamide must then be given, preferably, according to C. C. Chesterman's extensive experience, in the large doses in adults of 3.5 to 4 grammes, or 0.06 gramme per kilo, in a dilution of 1-40 intravenously at weekly or fortnightly intervals, or diluted further with an equal quantity of water intramuscularly, careful watch being kept for any visual disturbances which indicate temporary cessation of the treatment to avoid serious optic atrophy. In the South Sudan systematic search for and treatment of all sleeping sickness cases in camps has enabled the disease to be practically stamped out.

KALA-AZAR

The treatment of kala-azar has been greatly improved by the substitution of less toxic and more effective pentavalent antimony preparations discovered

by chemotherapy. A number of these have been carefully tested in the hospital of the Calcutta School of Tropical Medicine, and I. E. Napier has established that the best of them is neostibosan. He recommends daily doses of 0.2 to 0.3 gramme intravenously for ten days which will cure this formerly intractable and very fatal disease, with the result that the former case-mortality of 96 per cent in the Assam epidemic form and of over 80 per cent in the sporadic form of Bengal and other areas has been reduced to under 10 per cent. Moreover, by systematic search for and treatment of all cases in some villages the early incidence has been reduced from 121 and 127 in the first two years to 8 and 3 respectively in the fifth and sixth years; so with a sufficient staff it could be eradicated.

AMOEBIASIS

This is yet another example of the discovery of further effective drugs in the last decade; although emetine retains its place as the most active one in rapidly clearing up the primary symptoms, though not infrequently followed by relapses, in the case of amoebic hepatitis it is now generally agreed that it is still the only reliable quickly acting remedy. The value, in addition to the proof of the greater safety and efficiency, in already formed amoebic liver abscesses, of a combination of aspiration and emetine in place of the old deadly open operation in tropical countries, is testified to by the fact that an average yearly death rate of 98 from liver abscess in the British Army in India, in the decade up to 1907, has been succeeded by the absence of a single death from this cause in three consecutive recent years. Recent search for methods of preventing relapses of amoebic dysentery after emetine treatment has led to the trial of a number of arsenical and other preparations, and Acton and Knowles in Calcutta have found that the alkaloids of the old Indian remedy, kurchi bark from *Holarrhena anti-dysenterica*, is effective *in vitro* against the *E. histolytica*, but is too irritant intramuscularly, so Acton advises kurchi bismuth iodide orally. The arsenical preparation, stovarsol, is also of value to supplement emetine and has a tonic action. An expensive drug, yatren, has been much advocated by German writers in both amoebic and bacillary dysentery without much scientific basis, and A. C. Reed in America, and others, have found it of little value; but recently the last-named observer has found a new arsenical preparation, carbarsone, to be less toxic and more effective than other arsenical drugs in bringing about lasting good results in amoebic dysentery. It is given in 0.25 gramme doses twice daily for ten days in gelatine capsules, or it can be administered as an enema containing 2 grammes in 200 c.cm. warm 1 per cent sodium bicarbonate; toxic effects have not been observed.

CHOLERA AND SPRUE

In cholera no recent advances have been made in treatment, for bacteriophage has been found to be useless and, although it is claimed to have had a preventive action in Assam when added to drinking water, it failed in Bihar, so its value is not yet established.

In the other important bowel disease, sprue, a distinct advance has been made in the dietetic treatment, for though it has long been known that fats and much carbohydrate food were not well digested by sprue patients, Hamilton Fairley has worked out on these lines high protein diets of considerable value; the most convenient form is 'sprulac', a powdered milk containing the required quantities of the various food principles, which only requires to be added to hot water to be ready for use. Further, the dangerous pernicious anaemia complication has been found to yield to liver treatment, preferably combined with iron.

LEPROSY

In leprosy the principle of injecting soluble products of the active fatty acids of chaulmoogra and hydnocarpus oils—introduced by L. Rogers in 1915 and reported by him in 1917 to be much more effectual in the early stages of the disease, which are seldom seen under a system of compulsory segregation—is now in general use by injection in all parts of the world, either as the original sodium salts, such as alepol, ethyl esters as used since 1919 on a large scale by Dean and Hollmann in Hawaii, and by others in the Philippines or as cresoted pure hydnocarpus oil of Muir, which is the most economical plan. During the last few years Philippine observers have shown that the best result can be obtained by injecting ethyl esters directly into the skin lesions in drop doses in numerous places at one sitting. The improved treatment has led to a highly beneficial modification of rigid compulsion in a number of countries to enable early amenable cases to be attracted for treatment at outpatient clinics, and about 100,000 cases are being so dealt with at very slight cost yearly in India alone. In tropical Africa, with available land, the colony system, to allow the patients to be largely self-supporting while under treatment, is proving very successful. Some of the gold preparations used in tuberculosis have been tried in leprosy with variable results, but krysolgan appears to be of value intravenously in eye complication as advised by W. H. Hoffman. By seeking out and treating early cases among the household contacts of known lepers it should be possible to prevent the large majority of new cases going on to an advanced infective stage, only a small number of which are curable, and as patients with advanced infection rarely live and retain their infectivity for more than ten years, the systematic use of this plan might soon reduce the remaining sources of infection to easily controllable proportions, and so in a decade or two render the task of nearly eradicating leprosy much simpler.

YAWS

In the widespread yaws of the tropics the salvarsan group of remedies retain their position, but owing to their cost being prohibitive in the scores of thousands of cases requiring treatment yearly in extensive areas of Africa, Oceania and elsewhere, the far cheaper bismuth preparations have proved of immense service, such as bismuth tartrate of sodium and potassium in 0.2 gramme doses in freshly prepared boiled solutions intramuscularly at a cost of one-tenth of a penny per dose, or 6-grain doses of sodium bismuth tartrate. Other bismuth preparations are under trial, but further evidence about them is required.

DIETETIC DISEASES

There has been more theoretical discussion on ætiology than practical therapeutic progress during the last few years on beriberi and pellagra. It has been claimed that the latter is related to a deficiency of vitamin B₃, and Harriette Chick holds that the facts may best be explained on the hypothesis that some toxic substance derived from maize may be rendered harmless by the action of pellagra-preventive P-P factor, or vitamin B₃, in yeast, liver, milk and meat which are effective pellagra-preventing foods.

HELMINTHIC DISEASES

No very outstanding discovery has been made in the last few years in the treatment of helminthic diseases, but useful work had been done on the detailed use of well-established remedies with a few useful modifications. In hookworm disease a combination of safe doses of the two active remedies carbon tetrachloride and oil of chenopodium, or its active principle ascaridol, has proved to be best for use on a large scale; for example, a maximum dose of

2 c.cm. in adults of a mixture of 40 per cent oil of chenopodium and 60 per cent of carbon tetrachloride was given to 250,000 persons by H. R. O'Brien in Siam without a death due to the drugs. Recently tetrachlorethylene has been tried in Calcutta and found to be less toxic and safer in alcohol than carbon tetrachloride. It can be given in a 4 c.cm. dose with 1 c.cm. of oil of chenopodium well shaken up in two ounces of saturated magnesium sulphate at a cost of one half-penny. In schistosomiasis tartar emetic intravenously, and emetine intramuscularly in young children with small veins, hold their own, and the newer pentavalent antimony preparations do not appear to present any advantages, and are much more expensive.

ULCERATIVE CONDITIONS

Tropical ulcerative conditions of various kinds remain to be mentioned. In *oriental sore* due to *Leishmania tropica* tartar emetic and emetine hydrochloride are still commonly used, and another effective method is to inject around the margin of the sores two or three times weekly $\frac{1}{4}$ grain doses of berberine sulphate in 1 c.cm. sterile water. In the common sloughing *tropical ulcer* striking results have recently been reported in Uganda following the daily intravenous injection of 15 grains of calcium chloride in 10 c.cm. water in adults. In *velvet sore* the discovery of diphtheria bacilli has led to the effective use of the serum. In *climatic bubo* Hanschell has reported good results from protein shock produced by the intravenous injection every third day of from 100 to 500 millions of dead typhoid bacilli.

Artificial Pneumothorax

By J. ARTHUR MYERS, M.D.

(From the *Journal of the American Medical Association*, Vol. CIII, 27th October, 1934, p. 1299)

METHOD OF ADMINISTRATION

In collapsing the lung by this method, pure nitrogen, pure oxygen, carbon dioxide and sterile air have been used. Although these gases in pure form may have certain minor advantages, filtered air has been found to be the most practical and satisfactory.

Simple and inexpensive devices can be made or may be purchased for the administration of air into the pleural cavity. These are equipped with manometers that determine when the point of the needle is in the pleural cavity. When one is certain of this fact, a small amount of air, approximately 25 c.cm., is allowed to flow into the pleural cavity. If the manometer shows that the pressure is still definitely negative, another 50 c.cm. of air may be introduced. If the manometer readings are still good, one should continue to introduce small amounts, watching the manometer readings until approximately 200 to 250 c.cm. has been introduced. This amount suffices for the initial treatment in the case of an adult and should be decreased for children, according to the size of the chest. The second treatment should be administered in approximately forty-eight hours, and here again, with the same meticulous care, one should introduce only small amounts of air between manometer readings until approximately 300 c.cm. has been introduced, provided the pressure remains negative. The third treatment is administered about seventy-two hours after the second; the fourth about five days after the third. The subsequent treatments may be administered at weekly intervals. Later, many patients may have their intervals increased to ten days or two weeks. However, this must be determined by the rapidity with which the air is absorbed from the pleural cavity and by the degree of collapse one desires to maintain. When no adhesions are present, the lung collapses to

the desired degree without the use of positive pressure. When adhesions are present, one is justified in using slight positive pressure after the patient has been on treatment for some time.

Some workers later use high positive pressures in order to stretch the adhesions sufficiently to permit a satisfactory collapse. Others prefer never to use more than a slightly positive pressure because of the possibility of tearing adhesions.

COMPLICATIONS

The passing of a needle through the chest wall for the purpose of introducing air into the pleural cavity is attended by some dangers, which must be recognized by every physician administering this form of treatment. The first is that of gas embolus, which may result if the tip of the needle is in a pulmonary vessel when air is introduced. This accident may be avoided by refraining from the administration of air until the manometer readings indicate with certainty that the point of the needle is in the pleural cavity. Probably a far more common cause of gas embolus is the giving way of an adhesion at its pulmonary attachment, resulting in the tearing of pulmonary vessels in which there is negative pressure. Thus, air that has been introduced into the pleural cavity is readily sucked into these vessels and may be transmitted to the coronary or cerebral arteries. This is a most distressing complication and sometimes is fatal. Fortunately, it occurs rarely. In the administration of approximately 20,000 treatments during the past fourteen years I have seen five cases of gas embolism, only one of which was fatal. The last one occurred six years ago.

Another complication is spontaneous accidental pneumothorax. This may be due to injury by the needle of the visceral pleura and pulmonary tissue immediately subjacent, thus allowing air from the lung to leak into the pleural cavity. The more common cause of this complication is the giving way of an adhesion at its attachment to the visceral pleura, thus producing a fistula through which air passes from the lung to the pleural cavity. Again, spontaneous collapse of the contralateral lung is occasionally seen. Such accidents may occur at any time during the administration of treatment or during the interval between treatments. When the lung spontaneously collapses suddenly and a flap of visceral pleura serves as a valve to prevent the return of air from the pleural cavity to the bronchial tree, relief must be provided by removal of air in a short time to prevent death. I have seen only two patients who I believe died from spontaneous or accidental pneumothorax. In both, death occurred within a few minutes after the onset of symptoms and before a physician could reach them. Although there was no post-mortem examination and other physicians are inclined to believe that each patient died of cardiac failure, I am still of the opinion from the symptoms described by members of their families and other associates that death was due to spontaneous pneumothorax.

Another complication is fluid in the pleural cavity. Small serous effusion is seen very frequently in artificial pneumothorax patients. It probably would be found in every case if one searched diligently and persistently enough for it. The serous fluid that lubricates the pleural layers gravitates to the most dependent part of the pleural cavity when air is introduced. Such effusion is of no significance. Large serous effusion occurs less frequently. It is often accompanied by symptoms that closely simulate those of influenza but usually persist longer. After the symptoms subside, the patient regains strength and a sense of well-being in a short time. If not aspirated, the fluid may remain for weeks or months and apparently favours the formation of obliterative adhesions, which may make further treatment impossible. Fibrin bodies in the fluid are observed in some cases and cast dense shadows on the x-ray film.

Some large effusions that appear to be only serous in the beginning are later found to be infected with tubercle bacilli or other pyogenic micro-organisms, or both. Thus, empyema becomes a complication that is most serious when it is due to mixed infection. Empyema rarely if ever results from micro-organisms reaching the pleural cavity through the needle. The cause of tuberculous empyema is obvious. Mixed infections usually result from pleural fistulas, which allow pyogenic micro-organisms to pass from the lung into the pleural cavity.

When instituting artificial pneumothorax, one must keep under close observation the mediastinum, since in some persons it is very flexible. This may result in considerable respiratory and cardiac embarrassment. In some cases mediastinal hernia is seen. When the mediastinum is too flexible to allow satisfactory collapse of the diseased lung, there are methods of stabilizing it, such as the introduction of oil into the pleural cavity.

Occasionally febrile reactions result from artificial pneumothorax treatment. They are probably due, for the most part, to increased absorption of toxins as a result of the collapse of the diseased area. These usually are not serious and disappear in a short time.

During and immediately following the first treatment, the patient may experience a sensation in the chest that is difficult to describe but is often spoken of as 'heaviness'. This is not significant and usually lasts only a few minutes to an hour or so. During the first twenty-four hours after the first treatment there may be discomfort in the chest, which varies in intensity from a slight ache to excruciating pain. This is caused in most cases by adhesions. The pain may be controlled by codeine. Usually it is not present following subsequent treatments.

In some cases, when artificial pneumothorax is attempted, pleural adhesions are encountered. They may vary in size and extent from those which completely obliterate the pleural space to those which are only thin strands and stretch to such an extent that satisfactory collapse is obtained. Between these extremes are seen adhesions, which become definitely stretched but not enough to permit the closing of cavities or adequate collapse of the diseased area to allow a good clinical result. In many such cases, intrapleural pneumolysis is practised with great success. The adhesions are cauterized near their attachment to the parietal pleura, following which the lung often collapses in a satisfactory manner as artificial pneumothorax is continued.

In an occasional case, during the first few hours of treatment, air leaks through the needle track and causes subcutaneous emphysema. This is of no significance but may cause the patient some discomfort and considerable alarm. After the first treatment is administered, the physician should take time to discuss the various possibilities with regard to pain, subcutaneous emphysema, and so on. If this is not done, the patient's confidence may be lost if some of these possibilities actually occur.

EFFECT ON NORMAL AND DISEASED LUNG TISSUE

Since artificial pneumothorax was first instituted, much has been learned about its effect on normal as well as on diseased lung tissue. Through observations it has come to be looked on as a simple procedure rather than a drastic one, as it was at first thought to be. Careful observations have revealed the fact that no serious harm comes to normal lung which is kept under a state of collapse over a long period of time. Gardner has shown that alterations resulting from collapse of the lung consist of the development of fibrous tissue in the pleura and connective tissue coats of the blood vessels and bronchi. The degree of permanent changes caused by artificial pneumothorax in fifteen cases studied pathologically was found to depend on the extent and degree of injury by the tuberculous process. There are slight changes

in the circulatory system when artificial pneumothorax is instituted, but they are harmless. The slight deviations from normal sometimes observed in the electrocardiogram are due to pleural and mediastinal adhesions that have altered the position of the heart rather than to myocardial factors. Basal metabolism is not altered in a significant way. Therefore, artificial pneumothorax can no longer be looked on as a drastic procedure when indicated in the treatment of pulmonary disease. Of the various forms of collapse therapy, artificial pneumothorax is the simplest and yet the most effective.

Fortunately, diseased areas in the lungs, except consolidations, dense fibrosis and the like, collapse more readily than normal areas, owing to the fact that in such areas there is little or no diminution of contractility but marked impairment of expansibility. Thus, selective collapse actually occurs. This makes it possible in many cases to keep the diseased area well collapsed while a considerable part of the normal lung tissue is functioning.

ARTIFICIAL PNEUMOTHORAX IN DIAGNOSIS

Since artificial pneumothorax is a simple procedure and when carefully performed does no harm, it has been found to be a very valuable diagnostic procedure, especially in diseases of the mediastinum, pleura, lungs, ribs and chest wall when obscure conditions exist. It has been used to determine definitely whether interlobar empyema exists and whether true cavity formation is present in the lung, as well as in mapping out other pulmonary conditions.

ARTIFICIAL PNEUMOTHORAX IN TREATMENT

Pulmonary tuberculosis.—Formerly the indications for artificial pneumothorax were hæmorrhage, cavity formation, or extensive disease involving one lung. In recent years the indications have been extended. Not long ago a small area of disease in the opposite lung was looked on as a contraindication to artificial pneumothorax. However paradoxical as it may seem, disease in the opposite lung often improves following the institution of artificial pneumothorax on the side of the more extensive disease. Such improvement is probably due to several factors: First, by reducing the toxæmia the patient's general condition is definitely improved, giving the body a better chance to control the lesion in the contralateral lung. Second, the sputum is soon rendered negative or entirely disappears, so that the feeding of the opposite lung and other parts of the respiratory tract with tubercle bacilli is discontinued. Third, the effect of pneumothorax is not confined to the lung being treated but has a slight immobilizing effect on the opposite lung. In case the disease in the opposite lung does not come under control or in case a new lesion appears in it, partial bilateral artificial pneumothorax may be instituted with a good deal of success. The reserve lung capacity is so great that it is possible to collapse each lung to about one-half its volume without causing dyspnoea or other discomfort to the patient. A good many workers now look on minimal, progressive pulmonary tuberculosis of the reinfection type as a definite indication for artificial pneumothorax. Conditions that were formerly thought to be a contraindication, such as tuberculous laryngitis and enteritis, are no longer considered so, as they may improve if the pulmonary lesion is brought under control. Even in cases of co-existing pulmonary carcinoma, artificial pneumothorax may render the patient's sputum negative until death results from malignancy. Diabetes is not a contraindication; in fact, many diabetic patients with co-existing pulmonary tuberculosis now have their diabetes treated successfully by modern methods and their pulmonary lesions brought under control by artificial pneumothorax. One of my patients has been under treatment for both conditions since 1925.

The main contraindications for artificial pneumothorax are cardiac disease, asthma, severe grade of

emphysema with markedly reduced vital capacity, and extensive bilateral tuberculosis.

Rest has long been looked on as the most important factor in the treatment of a tuberculous lesion in any part of the body. Strict bed rest alone reduces the activities of the lungs very slightly. They continue breathing at the rate of approximately 25,000 times a day. This probably is one of the reasons why bed rest alone so often fails. With satisfactory collapse by artificial pneumothorax, the diseased organ is actually at rest. This treatment has two main effects on pulmonary tuberculosis. First, the growth of tubercle bacilli is definitely inhibited. Second, venous stasis and some blocking of the lymph circulation occur, which are believed to stimulate the growth of connective tissue and aid in healing. Thus, it is well known that the two factors so significant in the control of tuberculosis are present; namely, the inhibition of proliferation of tubercle bacilli and the stimulation of fibrosis. Relief from symptoms, such as cough and expectoration, fever, increased pulse rate and impaired digestion, is very quickly experienced in many cases.

When cavities are present and their walls are not too thick, artificial pneumothorax closes them by bringing the walls in apposition where they become adherent and are permanently obliterated. Thus artificial pneumothorax is a simple, harmless procedure and yet most effective in the treatment of pulmonary tuberculosis.

Unfortunately, most of the results of artificial pneumothorax treatment observed to date dealt with cases that were moderately or far advanced when the treatment was begun. The first object of artificial pneumothorax treatment is to render the sputum negative or to prevent a case with negative or no sputum from becoming positive, thus protecting the patient as much as possible against endogenous reinfection and protecting his associates and the community against contamination with tubercle bacilli. By the time the disease has become moderately or far advanced most patients have positive sputum, whereas in the minimal stage this is true of only approximately one-third.

The Committee on Treatment of the American Sanatorium Association, consisting of Douglass, Peters and others, found that at the termination of artificial pneumothorax as recommended by the physician 66.1 per cent had negative sputum, whereas among those whose lungs re-expanded before their physicians recommended it only 46.9 per cent had negative sputum. A much higher percentage would have had negative sputum if the treatment could have been instituted while the disease was in the minimal stage. They classified 405 patients with reference to sputum at the termination of treatment according to the condition of the treated lung before collapse. Approximately 11 per cent more were negative when slight or no cavitation was present before treatment was begun than among those who had definite cavity formation. Thus, the less disease and destruction done before the lung is collapsed, the better the chances of rendering the sputum negative to tubercle bacilli.

In most groups of cases reported, those in which collapse was possible have shown a 20 per cent or more better chance of becoming well or able to work than those who were not treated by this method. Thus, the treatment is very much worth while even in moderately or far advanced cases, yet many such cases require long periods of bed rest in addition to artificial pneumothorax treatment.

Although the treatment of moderately and far advanced cases by pneumothorax has been found to be far superior to previous forms of treatment, such as strict bed rest, still it was not entirely satisfactory because the patients had often lost their best chances of recovery before the treatment was begun. Therefore the results obtained leave much to be desired. Moreover, when cavities have been formed, a high percentage of patients were disseminating tubercle bacilli to their associates.

Many artificial pneumothorax workers are now of the opinion that this form of therapy is most valuable for patients with minimal lesions. In the past, such lesions have been diagnosed so rarely, and when found so many workers believed that pneumothorax was too drastic for them, that very few reports show the results of artificial pneumothorax on minimal lesions. However, with modern methods of diagnosis, including the tuberculin test and the x-ray film, particularly when used as a part of the periodic examination in the physician's office and in special case-finding campaigns, the percentage of cases found presenting minimal progressive pulmonary tuberculosis is definitely increasing. The disease is found before it has produced symptoms, before great destruction of lung tissue has occurred and before tubercle bacilli are being eliminated. In these cases, physical signs usually are absent. The diagnosis is made largely by the tuberculin test and the roentgen examination. One is not justified in instituting artificial pneumothorax every time a shadow, minimal in extent, is found in the lung. The roentgen examination is not sufficiently refined to determine on first examination with a high degree of accuracy whether the lesion is of long standing and well controlled or is recent and progressive. To collapse a lung containing the former type of lesion is to do definite injustice to the patient and much unnecessary work. Therefore, before instituting collapse therapy one should keep the lesion under observation long enough to determine that it is progressive. Whenever this fact is established, no matter how small the lesion, it is none too early to institute artificial pneumothorax. To wait until the disease has become extensive, cavities have formed and adhesions are binding the lung at least in part to the chest wall is just as ridiculous as to wait until the appendix has ruptured before performing appendectomy.

I now have approximately fifty patients under observation whose artificial pneumothorax was instituted when the disease was minimal. To date, the results in this group are superior to those in other groups under my care who had artificial pneumothorax instituted after the disease had become moderately or far advanced. The results are also superior to those of other groups of minimal cases whom I have observed as they were treated by bed rest alone. I am convinced that, if the lesions are minimal when the treatment is begun, strict bed rest is necessary for only a short time, if at all, and in most cases the period of hospitalization when necessary can safely be limited to a few weeks. Thus, from the standpoint of rendering the sputum negative, of obtaining good results, that is, restoring good working capacity in a high percentage of cases and saving of the patient's time, the earlier in the course of the disease the treatment is begun, the better.

Any physician practising artificial pneumothorax therapy to a considerable extent will be confronted with lesions in all stages from minimal to far advanced. The answer to the frequently asked question when should artificial pneumothorax be instituted is to attempt it in all unilateral cases at the earliest possible moment after the disease is known to be progressive, no matter how minimal or how advanced except when the foregoing contraindications are present. When both lungs are involved, that of the more extensive and progressive disease should be collapsed, provided the better lung is or becomes sufficiently clear to carry on the necessary respiratory functions. The physician frequently meets considerable disappointment, since a fair percentage of patients in whom artificial pneumothorax is definitely indicated as determined by the extent of the lesion have extensive or complete obliteration of the pleural cavity through the development of adhesions. For this group, strict bed rest is indicated and should be supplemented by phrenic exeresis, extrapleural thoracostomy and extrapleural pneumolysis if necessary. Even though the prognosis is not

as favourable in far-advanced cases, artificial pneumothorax should be attempted when the better lung appears sufficiently free from disease. Good results are obtained in enough such cases to justify giving every patient the advantage of a trial of artificial pneumothorax. Obviously, the less extensive the disease, the better the general condition of the patient; and the fewer the extrapulmonary complications, the better is the patient's risk.

When one sees the mother with extensive pulmonary tuberculosis, first detected by reason of symptoms a few days or a few weeks after delivery, one can be reasonably certain that the disease did not develop suddenly; that in all probability it had been present in a detectable form long before the pregnancy began. Therefore, many disasters can be avoided when all physicians insist on a careful chest examination, including the x-ray film, of every pregnant woman as early in the course of pregnancy as possible. In the Minneapolis General Hospital and Minnesota General Hospital, there is close co-operation between the obstetric and the chest services. Every woman who presents herself for obstetric care is referred to the chest clinic, where the tuberculin test is administered and x-ray films of the chest are made of all positive reactors. Obviously, if the private practitioners of this country, who do the bulk of medical work, will adopt the same procedure, they will be rewarded many times for their effort through finding in the chest of pregnant women tuberculous lesions previously unsuspected. Often these lesions can be successfully treated by artificial pneumothorax and the pregnancy allowed to continue without any harm to the mother. In our experience, delivery is not rendered more difficult after the institution of artificial pneumothorax. The mother's sputum is prevented from becoming positive or, if positive when the lesion is detected, it may be rendered negative. Although it does not seem wise for such mothers to nurse their infants, they may remain in the home as safe associates of their families. The physician who detects and treats such cases renders a service of inestimable value to the patient, the family and the community. He not only often saves the mother's life or prevents a long period of invalidism, but he protects her children, her husband and many members of the community against contamination with tubercle bacilli.

In the past, artificial pneumothorax has been used very extensively among ambulatory patients. However, most of these patients were submitted to a long period of bed rest after artificial pneumothorax had been instituted. They were later allowed to become ambulatory and return to work, while the artificial pneumothorax treatments were continued. In recent years it has been found that many patients with pulmonary tuberculosis may have artificial pneumothorax instituted without being subjected to strict bed rest, or at most to a few weeks of such rest, while the treatment is being instituted. Reports of the results of such treatment coming from various parts of the world, including a few centres in this country, are very encouraging. Patients on ambulatory treatment from the beginning must be very carefully selected. They will be found among individuals who have minimal or moderately advanced unilateral lesions which are definitely progressive but which have not yet caused serious illness. There should be no significant tuberculous or non-tuberculous complications. The sputum may be negative or positive. If it is negative or none is present, one may direct the disease toward healing rather than let it go on progressing. If it is positive, collapse will often render it negative or entirely absent in a short time. The physician often sees patients with advanced disease, mostly unilateral, who refuse hospitalization or do not require it; that is, their general condition is good, they have reasonably good working capacities, but there is always the danger of their bacilli spreading to other parts of the body and to their associates. To collapse the diseased lungs of

such patients while they remain ambulatory is a service not only to them but to their communities.

Tuberculosis is frequently seen among elderly persons. While the disease may not cause them serious illness and may not cut short their lives, it may be very dangerous to their associates. In such cases artificial pneumothorax, when possible, protects the community against the spread of their tubercle bacilli while the patients remain ambulatory.

Thus there is a considerable percentage of patients with pulmonary tuberculosis who may now be treated with a short or no period of hospitalization. They avoid the mental complications that so frequently develop from long periods of hospitalization, they are permitted to enjoy their homes, and they continue their earning capacity. We now have under treatment approximately seventy-five such patients who in times past, when we believed it was necessary to hospitalize them, would have cost the taxpayers approximately \$75,000 a year. To date, the results have been as good as those obtained in other cases that were treated both by strict bed rest and by collapse. Moreover, the extension of this work to large numbers of patients makes available beds in institutions, where patients with disease so advanced that it cannot be treated successfully may be isolated.

Artificial pneumothorax is indicated in children only when the lesions are of the reinfection type. Unfortunately, unless tuberculin tests have been administered periodically it is difficult to differentiate between the lesions of the first infection type in the inflammatory stage and lesions of the reinfection type in the infiltrative stage. However, a period of observation often aids in such differentiation. Lesions of the first infection type usually cause slight or no symptoms. They reach their maximum development in a short time, remain stationary, and then begin to resolve, whereas lesions of the reinfection type usually show a tendency to increase in size sooner or later, cause symptoms and present definite evidence of fibrosis, cavitation or other complications. However, paradoxical as it may seem, in some cases of reinfection, there is rarely, if ever, any danger of other conditions. There is rarely, if ever, any justification for inducing artificial pneumothorax in the case of a child who has the first infection type of tuberculosis. This statement applies also to the first infection type of tuberculosis in adults. Among 149 children whom we have observed with the first infection type in the inflammatory stage over a period of one to twelve years at the Lymanhurst School, we have not instituted artificial pneumothorax in a single case. When the lesion is found to be of the reinfection type and is demonstrated to be of a progressive nature, no matter how small it is or how young the child, artificial pneumothorax is recommended. This procedure does not lead to deformity unless complications arise, such as empyema; therefore one need have no hesitancy in administering artificial pneumothorax during the period of childhood.

The question which artificial pneumothorax patients most frequently ask the clinician is when may I discontinue the treatments? Unfortunately, symptoms, physical signs and x-ray films are not safe criteria in answering this question. No one can determine with certainty when the tuberculous lesion is so well under control that it will not reactivate if allowed to re-expand. In the earlier days of this work, the lung was usually allowed to re-expand too soon. The disappearance of symptoms and the marked improvement in the patient's general condition led to a false sense of security on the part of the patient as well as of the physician. Experience soon taught us however that, if permanent results were to be obtained, the lung should be collapsed over a long period. No one can lay down a rule as to just how long the treatment should be continued. This is a problem that must be solved for each individual patient. It must depend on several factors, such as the extent of disease when the treatment is instituted, size of the cavities, presence of tubercle bacilli in the sputum, tuberculous and non-tuberculous complications, and the patient's general

condition. In minimal cases one hesitates to allow the lung to re-expand in less than two years. In moderately or far advanced cases the lung should be kept collapsed for a period of at least three to five years and in many cases much longer; in fact, when large cavities are present and the involvement is extensive when the treatment is instituted, it is doubtful whether the lung should ever be allowed to re-expand. The red cell sedimentation rate, as recommended by such workers as Cutler, may prove a valuable index on this subject. He is of the opinion that, by observing this rate carefully and periodically throughout the course of treatment, one can determine with a reasonably high degree of accuracy when the lesion is well under control.

A very unfortunate fact about artificial pneumothorax work is that one is not able in all cases to continue the collapse as long as one desires. In a fair percentage of patients, adhesions develop in the pleural cavity and finally obliterate the pneumothorax space. The development of such adhesions may be rapid, so that the space is lost in a short time, or it may be slow, thus permitting one to continue the treatment with a partial collapse over a long period of time. When it is obvious that such adhesions are developing, particularly if the space is being lost fairly fast, oleothorax should be instituted at once. In such cases gomenol (an oil obtained from *Melaleuca viridiflora*) may be used, although many workers are of the opinion that sterilized liquid petrolatum or olive oil has an equally good effect. Thus, through the replacement of air with oil, further development of the obliterative adhesions is prevented or definitely retarded and the lung may be kept collapsed over the desired period of time. Because of complications that sometimes arise with oleothorax, it is not yet considered a substitute for artificial pneumothorax except in special cases.

Other pulmonary and bronchial conditions.—Artificial pneumothorax has been used to some extent in the treatment of bronchiectasis and pulmonary abscess. Although it has not been found as valuable in these conditions as in pulmonary tuberculosis, it is very much worth while in properly selected cases.

Lobar pneumonia.—One of the recent developments in artificial pneumothorax work has been its administration to patients suffering from lobar pneumonia. In 1921 Friedman reported the results of artificial pneumothorax in seven cases of pneumonia. Since that time, several workers in other countries have used it and the reports to date, although they cover a limited number of patients, are very encouraging. The more recent observations were reported by Coghlan in January 1932 and by Li in September 1932. Each treated six cases. The treatment resulted in almost immediate relief of symptoms, such as fever and pain. In short, artificial crises appeared soon after the treatment was instituted. In fact, fifty cases have been reported in other countries, with forty-seven recoveries.

In this country, Moorman of Oklahoma City instituted artificial pneumothorax in the treatment of two cases of pneumonia in 1930. Lieberman and Leopold of Philadelphia reported the results of their work on therapeutic pneumothorax in experimental lobar pneumonia in dogs in March 1934. They produced lobar pneumonia in thirty-six dogs, eighteen of which were used as controls and eighteen were treated by artificial pneumothorax. Of the treated dogs, fifteen recovered and three died; of the untreated dogs, five recovered and thirteen died. Two of the treated dogs probably died from another cause; thus, the results of treatment were exceptionally good. Of this work Stengel says:

These results were so confirmative of the clinical experiences reported by several persons . . . that we proceeded to try the treatment in man.

Again he says :

While this method seems to be a step of value in the treatment of pneumonia, I think it should be emphasized and re-emphasized that this is not a treatment which in the state of our present knowledge should be regarded as applicable to influenzal pneumonias or diffuse streptococcal pneumonias, nor should it be used, in my opinion, in any case of pneumonia that is recognized at the time as being in any degree bilateral, even with a small lesion on the opposite side.

In May 1931 Blake of New Haven reported his results in the treatment of twenty early cases of pneumococcal lobar pneumonia by artificial pneumothorax on or before the fourth day of disease. Eleven of his patients had a free pleural space, and all recovered promptly by crisis or rapid lysis with no complications except a sterile pleural effusion in one. In the remaining nine cases, pre-existing pleural adhesions were present, which prevented adequate collapse. Although none of these patients died, the disease appeared to run its natural course and two developed empyema.

In June 1931 Behrend and Cowper reported the results of treating eleven patients with unilateral lobar pneumonia by artificial pneumothorax. Nine patients recovered, and two died, but neither of the fatalities could be directly attributed to the pneumothorax.

Stengel says :

The very prompt development of a crisis in patients with marked but early lobar pneumonia and the almost immediate improvement in all subjective symptoms is very striking. Taking all the cases together the mortality of pneumonia under this treatment will probably be distinctly limited but it is to be remembered that certain complicating conditions, such as bilateral involvement, the presence of dense pleural adhesions, etc., interfere with the appropriateness and effectiveness of the treatment and possibly these cases may also be those which contribute to elevating the mortality rate of this disease under any kind of treatment. If the mortality from pneumonia were in no degree lowered by pneumothorax, it might still be said that the prompt improvement and the speedy termination of the disease secured by pneumothorax treatment would still constitute a very decided advance.

SUMMARY

1. Forlanini in Italy collapsed a diseased lung in 1892. Murphy of Chicago in 1898 reported a group of cases treated by artificial pneumothorax.

2. Filtered air to the amount of from 200 to 250 c.c. is introduced, under carefully observed manometer readings, into the pleural cavity as an initial treatment. The second treatment is given forty-eight hours later; the third seventy-two hours after the second, and the fourth about five days later. The interval between subsequent treatments depends on the extent of collapse and the rate of absorption of air.

3. The complications are gas embolus, spontaneous or accidental pneumothorax, serous effusion, empyema, mediastinal hernia, febrile reactions, pain and subcutaneous emphysema.

4. Artificial pneumothorax has no deleterious effect on normal lung tissue or the other organs, such as the heart. Diseased tissue collapses more readily than normal tissue, so that selective collapse may result.

5. Artificial pneumothorax may be used as a diagnostic measure.

6. Hemorrhage and minimal progressive to far-advanced unilateral pulmonary tuberculosis are indications for pneumothorax. Even bilateral disease, if one lung is not too extensively involved, responds to pneumothorax treatment. Contraindications are cardiac disease, asthma, severe emphysema and advanced bilateral tuberculosis.

7. In moderately and far-advanced cases, successful pneumothorax shortens the period of bed rest necessary, renders the sputum negative, and closes cavities if the walls are not too thick. In minimal progressive lesions it prevents the sputum from becoming positive or, if positive, renders it negative and controls the disease and frequently obviates hospitalization and strict bed rest.

8. Pregnancy is an indication for rather than against pneumothorax, if the disease is discovered at that time because of the beneficial effect for the patient and the possibility of changing the sputum to negative.

9. Treatment by pneumothorax with the patient remaining ambulatory is possible for selected cases, including elderly persons.

10. Pneumothorax is indicated in children if the lesion is of the reinfection type.

11. Several factors must be kept in mind when discontinuation of pneumothorax is acceded to. Minimal cases should continue at least two years, and moderately or far-advanced cases from three to five years or even longer.

12. Oil may be substituted for air if adhesions are forming and obliterating the pleural cavity.

13. Pneumothorax is used to some extent in bronchiectasis, pulmonary abscess and lobar pneumonia.

The Treatment of Post-Operative Retention of Urine

By N. R. BARRETT, M.Chir. (Camb.), F.R.C.S. (Eng.)
(From the *Lancet*, Vol. II, 10th November, 1934, p. 1046)

THE treatment of post-operative retention of urine is often delayed and indefinite and the condition worries the patient. There are many occasions on which the worst part of an operation, in the opinion of the patient, is the period after the return of consciousness when the discomfort of nausea and vomiting is aggravated by inability to micturate.

Textbooks of surgery are unanimous in their opinion that spontaneous micturition must be established as soon as possible after operation, but the treatments they advise for those patients who have difficulty are not always immediately successful. There is no doubt that the most simple and immediate relief is given by passing a catheter, but this is seldom done because of the fear that the patient may develop cystitis and subsequent infection of the kidneys, and because it is taught that once a catheter has been passed it may be necessary to repeat the procedure on several occasions. During the past year an effort has been made in the wards of the surgical unit of St. Thomas's Hospital to determine the possible advantages of using a catheter whenever it may be necessary, and to estimate the dangers to which the patient is exposed as a result of this practice. Incidentally certain other features were investigated and some will be briefly considered.

In a control series of 414 patients operated upon for general surgical conditions, the incidence of post-operative retention was 9 per cent in males and 7 per cent in females. The patients with retention were treated by giving hexamine grs. 15 and repeating the mixture in 20 minutes if the first dose was not successful.

It is well known that operations upon the perineum or pelvic organs are more likely to be associated with post-operative retention than any others because relaxation of the perineal muscles is inseparably connected with the voluntary development of micturition. It has been shown that the process starts with rhythmical contractions of the bladder musculature, and this is followed by a relaxation of the internal and external sphincters. Passive increase in the intravesical pressure does not influence the sphincters, and therefore straining by the abdominal muscles is not successful as long as the sphincter supplied by the

SOME NOTABLE EPIDEMICS.—By H. H. Scott, M.D., F.R.C.P. (Lond.), D.P.H., D.T.M. & H. (Oamb.), F.R.S.E. 1934. Edward Arnold and Company, London. Pp. xix plus 272. Price, 12s. 6d.

This is another very good example of the saying 'What the eye does not see the heart does not crave', or to put it in the words of the advertising 'profession' it is a book that creates its own demand. Before we received this book, we were unaware, though others may not have been, of the serious gap in the medical literature of the day that it has now partially filled, and we have no doubt that the author has already received many suggestions that he should follow up this book by another, 'More Notable Epidemics'; the demand already exists.

The book is an anthology of recent, or, rather, comparatively recent, British epidemics. The author was lured away from his original intention of limiting the period to fifty years, that is to say to the bacteriological era, by his desire to do justice to a latter-day Hippocrates, Dr. John Snow, who has not in the author's opinion received sufficient recognition hitherto, and he has therefore included the 'Broad Street pump' cholera outbreak of 1854. John Snow was an astute observer who had the misfortune to be born a little ahead of his time; his ideas regarding the spread of cholera and other epidemic diseases were considered 'peculiar' in his day, but time has shown that they were strikingly correct.

The epidemics that are described are practically all milk-, water- or food-borne; epidemic influenza, 'the standard epidemic of Nature', is not included. The author's viewpoint is the present and he has not attempted to correct the perspective, otherwise he would not have included the Holborn and St. Pancras 'Sonnet' outbreak of 1933; in this 13 persons were attacked and only two died. This comment is not made in any spirit of criticism, as this outbreak is a good example of a food-borne epidemic; it was due to individual carelessness and some laxity in the preparation of food in a food shop. It is also an example of a piece of medical detective work that could not possibly have been carried through without the aid of bacteriology.

To Dr. Harold Scott, sanitarians throughout the world, and especially those in the tropics, owe an insoluble and steadily-mounting debt, not only for this recent contribution but for many others and particularly for his invaluable annual summaries of colonial medical reports. It may reasonably be claimed that he is one of the leading medical writers of the day, and as such he is certain to attract the envy and spite of the lesser fry amongst this community; he will therefore understand how to treat the following carping criticism of a disappointed admirer:—The impression that we gained from reading the introduction was that, after finishing the book proper, the author decided that he must write an introduction of about ten pages and proceeded to cover these in a very tired manner. The mental processes that preceded his choice of material for inclusion in his anthology may have been interesting to him, but are very boring to the reader who is interested only in their result, and his summary of the nineteen chapters seems to us quite unnecessary; there is a full contents list. The facetiae that are introduced here and there throughout the book are often forced and inappropriate. We appeal to Dr. Scott, the master of compression, to turn to page 2 of his book and say whether he really considers that the book would be one scrap the poorer if he had omitted the six central paragraphs of this page; 'prolixity and vain repetition' are his own words. With the exercise of economy of words room might have been made for a few more notable epidemics without increasing the length of the book. Then, on a point of accuracy, surely it was in 1883 and not in 1886 that Koch discovered the cholera vibrio? Finally, we think that

he might have spared us the cacophonous phrase 'epidemiologically epochal'.

Nevertheless we will repeat, not vainly we hope, that Dr. Scott has made another invaluable contribution to medical literature; this book which in places is as interesting as any detective novel should, and we think will, find a place in every medical library in this country and be read extensively.

L. E. N.

A MANUAL OF DISEASES OF THE EYE.—By Charles H. May, M.D., and Claud Worth, F.R.C.S. (Eng.). Seventh Edition, 1934. Baillière, Tindall and Cox, London. Pp. viii plus 505, with 350 figures and 23 plates. Price, 15s.

This is the seventh edition of this excellent manual which has been extensively revised and in some parts rewritten. At the same time the size of the book has only increased by 30 pages and the author of the present edition, Montagu L. Hine, F.R.C.S., has been able to make these additions by omitting parts included in previous editions.

As this is a book which is written principally for students, this is a wise procedure as the original aim of the book was to describe the fundamental facts of ophthalmology without going into detail to describe rarer conditions.

The new additions on detachment of the retina, orthoptic treatment, colour vision and contact glasses are simply and excellently described. In addition, there are numerous changes throughout the book on diseases of the lacrimal apparatus, glaucoma and cataract. As the book is extensively used in Medical Colleges in India, it is a pity that more space has not been given to certain eye diseases which are common in tropical countries, such as epidemic-dropsy, glaucoma, superficial punctate keratitis as seen in India, and leprosy. However, the book is an excellent one, and the addition of new material will increase its usefulness, and we can cordially recommend it to all medical students and general practitioners.

E. O'G. K.

CATARACT: ITS ETIOLOGY AND TREATMENT.—

By C. A. Clapp, M.D., F.A.C.S. 1934. Henry Kimpton, London. Pp. xi plus 254. Illustrated with 92 engravings. Price, 18s.

THE amount of literature that exists in reference to the normal crystalline lens and its disorders is enormous, yet it is surprising that no work in English has so far been published; for such a book there is a distinct need.

With this end in view the author has produced a very valuable and concise work. The book consists of 25 chapters which are devoted to the embryology, comparative anatomy, anatomy, physiology and chemistry of the lens, as well as to the pathology and treatment of cataract and the care of the cataract patient.

The chapters on the embryology and comparative anatomy of the lens have been admirably written by Miss Ida Mann.

Dr. Clapp has succeeded in writing a most excellent, interesting and immensely practical book embodying facts that seem to be well established and the most approved methods of treatment.

The illustrations are excellent and numerous, and at the end of each chapter is an extensive bibliography. A work on cataract will always be of interest to medical men in India and it is a pity that no mention has been made of syphilis, malaria and ankylostomiasis in the pathogenesis of cataract, as these diseases are common causes of toxic cataract in India. The treatment of monocular cataract has also been overlooked.

The author deserves the greatest praise on the excellence of his work which will be found of great value to ophthalmologists as well as to medical men

in general, for the treatment of cataract forms a large part of the daily routine of the surgeon working in India, and we strongly recommend the book to all who are interested in this fascinating branch of surgery.

E O'G. K.

DISEASES OF THE SKIN. (CATECHISM SERIES).

—By J. F. Smith, M.A., M.B. Second Edition. E. and S. Livingstone, Edinburgh. Pp. 86. Price, 1s. 6d. Postage, 2d.

This is an outline of the bare essentials of diagnosis, treatment, etc., of skin diseases arranged in the form of question and brief answer. The book is only of use for students for the purpose of rapid revision before an examination, and only those students will be able to benefit from its use, who are endowed with the faculty of rapidly committing to memory anything they read, for there are no explanatory passages, typical examples and cases quoted which serve to fix facts in the mind of the average individual.

P. A. M.

A MANUAL OF MENTAL DISEASES. A TEXTBOOK FOR STUDENTS AND PRACTITIONERS IN INDIA.

—By C. J. Lodge Patch, M.C., Major, I.M.S. 1934. Ballière, Tindall and Cox, London. Pp. vii plus 332. Price, 10s. 6d.

It is rare for a manual of mental disease to be written in a language that is readily understandable by the medical student, and by the general practitioner of medicine. It is equally rare for such a book to create an interest in the somewhat obtuse subject with which it deals and further to impress the reader with the practical professional knowledge and sound common sense which the author presents his subject. And yet this manual possesses all these characteristics. Added to this the author has the clarity of a gifted writer who has taken the trouble to weigh the value of each written word. In simple language, Major Patch describes the healthy mind and how his disorders deviate from normality. In succeeding chapters the clinical recognition, including both physical and mental symptoms, of the psychoses is clearly described. The causation of prophylaxis of mental disease with the steps which should be taken by parents, teachers, and family physicians to diminish the risk of the possible break-down in a predisposed child are adequately dealt with. The concluding chapters on diagnosis, prognosis and treatment are especially valuable. This book is described as a textbook for students and practitioners in India and admirably does it fulfil this rôle. Lucky is the student whose teacher advises him to follow this textbook along with the teacher's own prescribed course of instruction. There is no textbook in India on mental disease comparable to it in merit. Holding this view, perhaps the reviewer may be pardoned for adding a few criticisms.

It is regrettable that the author did not include a brief chapter—even if only of one or two pages—on the pathology of mental disease—covering what little is actually known and indicating what is summarized. For pathology is the foundation of all knowledge and enquiry and research would best be stimulated if the gaps in our knowledge were laid bare. The author has also deliberately excluded the psychoneuroses. His reasons were weighty—and yet such is the charm and the clarity of the author's writing that there is a distinct sense of loss at this omission. Moreover, the wide distribution of the psychoneuroses and the frequency with which the young graduate is called upon to deal with them renders it imperative that he should hear of these disorders from the physician and from the alienist alike. For the psychoneuroses form a common meeting ground on which these two groups of teachers can come to grips. It is hoped that in the next edition a few chapters or an appendix will

be added on the psychoneuroses, or, in the alternative, that the author may publish a second small volume dealing with such conditions. It would also be of advantage if a few line diagrams, such as the author probably uses in his lecture room, could be included. As has already been indicated no student or practitioner of medicine who desires enjoyment, interest and instruction should miss reading this most instructive and attractive of textbooks.

H. S.

A TEXTBOOK OF HISTOLOGY.—By A. A. Maximow and W. Bloom. Second Edition. 1934. W. B. Saunders Company, Limited, Philadelphia and London. Pp. 662 with 530 Illustrations. Price, 30s.

PROFESSOR MAXIMOW has left his mark in medical history as a cytologist of the first rank, and it is therefore fortunate that he should have left behind him when he died sufficient manuscript and notes to enable a book on histology to be published in his name. The historical value of such a book would in any case be considerable, but it is greatly to the credit of the second author that this book has proved of such practical value as well, that another edition was demanded within four years.

We are not at all surprised that this book should have proved so popular, as it is in every way a satisfactory one. The plan of arrangement usual in a book of this kind is followed. The descriptions are clear and the illustrations well chosen; the latter maintain a nice balance between realism and clarity, and the half-dozen coloured plates are especially useful.

The sections on the blood, on the blood-forming and destroying tissues, and on the spleen claimed most of the reviewer's attention. These sections are particularly good, though emphasis is usually laid on the theory favoured by the late Professor Maximow. For example, the present author is very hard on all the pluralist theories of blood formation, and one would gather from reading these sections that the unitarian theory of the common origin of all blood elements from a single stem cell, the *hemocytoblast*, was universally accepted, whereas this is not the case; the blood histocyte is looked upon as a purely pathological cell which seldom, if ever except during the agonal phase, appears in the general systemic circulation. The references to the blood-destroying tissues are perhaps not as full as one might wish for, but this is a subject on which present-day knowledge is not very complete.

The section on the spleen has been revised by Professor Talaferro; it would appear that this organ is coming to be looked upon as the special preserve of protozoologists.

The second edition contains a number of useful references; these, we are told in the preface, were included by special request. They have added considerably to the value of the book from the point of view of post-graduate readers. On the whole, it is a very excellent book and one that we can thoroughly recommend to teachers and students.

L. E. N.

A TEXTBOOK OF HISTOLOGY.—By Harvey Ernest Jordan, A.M., Ph.D. Sixth Edition. 1934. D. Appleton-Century Company, Incorporated, London. 1934. Pp. xxvii plus 738 with 610 Illustrations. Price, 30s.

THE sixth edition of this well-known textbook on histology has been thoroughly revised and brought up to date. The most extensive revisions and additions both in the text and figures are in the sections dealing with blood, the reticulo-endothelial system, the endocrine tissue, striped muscle, neuroglia, nervous tissue, the reproductive systems and the lymphoid organs. In spite of many additions the author by

judicious pruning has kept this edition within the limits of the former editions. The book will prove of great value to all students of medicine particularly to those who have some knowledge of elements of histology.

C. L. P.

A TEXTBOOK OF PATHOLOGY.—By William Boyd, M.D., M.R.C.P. (Ed.), F.R.C.P. (Lond.), F.R.S.C. Second Edition. 1934. Henry Kimpton, London. Pp. 1047 with 416 engravings and 8 coloured plates. Price, 45s.

MANY changes and additions have been made in the second edition of this excellent textbook. The order of the first part of the book has been entirely altered and many sections have been re-arranged. Certain chapters, especially those dealing with tuberculosis, immunity and allergy, and bacterial infections have been largely rewritten, and much new material has been incorporated in this edition. Major alterations and additions have also been made in connection with animal parasites, teratomas, the origin of pigmented moles, focal infection, rheumatic fever, the bacteriology of influenza and of whooping cough, the relation of cholesterol to atheroma and coronary sclerosis, silicosis, amœbic dysentery and agranulocytic anæmia. All the usual subjects are included and dealt with in an efficient manner.

A number of new illustrations have been added which greatly enhance the value of this work. We can strongly recommend this book to those who desire a thorough basic knowledge of the subject.

C. L. P.

ANNALS OF THE PICKETT-THOMSON RESEARCH LABORATORIES. INFLUENZA. PART II. Volume X, Monograph XVI.—By D. Thomson and R. Thomson. May 1934. Published for The Pickett-Thomson Research Laboratory by Baillière, Tindall and Cox, London. Pp. xix plus 916 (from 641 to 1557). Price, £3 3s.

THIS volume is the largest that has been issued by the Pickett-Thomson Research Laboratory, and it completes what must be the most comprehensive monograph on influenza yet published. The monograph consists of 1,455 pages of which about eight hundred are in this volume.

The bacteriology of influenza was dealt with in the first part of this monograph; part II deals mainly with the clinical aspects and epidemiology, and in this respect differs from the majority of the *Annals*. About three hundred pages are devoted to the sequelæ and complications of influenza; the subject of pneumonia as a sequel of influenza occupies more than a quarter of this section and is dealt with in all its aspects. There are short sections on the influence of the disease on the physiological functions peculiar to women, and on its association with pulmonary tuberculosis; it is interesting to note what a complete reversal of opinion there has been in recent years on the question of influenza as a predisposing factor in pulmonary tuberculosis. There appears to be no statistical evidence to show that 'influenza infection' does to any noteworthy extent predispose persons to tuberculosis infection.

The pathology of influenza forms another large section. In the section on epidemiological data, a very good summary of the various pandemics is given and such important subjects as the periodicity of influenza epidemics are discussed with full data collected from a number of sources; it is interesting to note which countries provide the most elaborate data. The section on the possible modes of transmission is a short and rather disappointing one. There is a section each on vaccines and sera in treatment and prophylaxis, and one on preventive measures generally, in influenza epidemics. Treatment is given a section of about

forty pages; we see that S. U. P. 36 is mentioned here, but is not referred to in the authors' summary.

The usual practice of giving a summary at the end of each section is followed, and at the end of the volume there is a thirty-page summary which the reader will find most valuable. There are about 4,500 references to the literature, and both an authors' and a subject index.

The authors undertook a colossal task and they are to be congratulated on the way they have accomplished it. They will have the satisfaction of knowing that for many years to come their monograph will be the standard work of reference on influenza, alike to bacteriologists, clinicians and sanitarians.

L. E. N.

RADIUM AND CANCER. A MONOGRAPH.—By H. S. Souttar, D.M., M.Ch. (Oxon.), F.R.C.S. (Eng.), M.D. 1934. William Heinemann (Medical Books) Limited, London. Pp. xiii plus 387. Illustrated. Price, 21s.

RADIUM has now taken so very important a place in medical treatment—in the widest sense—that the practitioner can no longer take the attitude that it is a subject entirely beyond his comprehension and one that he must leave to the specialist. We are not suggesting that every practitioner should have a gramme or two of radium at his disposal to experiment with, but he must understand something of the principles of its action and of its possibilities in the treatment of cancer, otherwise he will not be in a position to advise his patients when the occasion arises. Even the surgeon is seldom equipped with the fundamental knowledge of atomic physics that is necessary if he is to use radium intelligently, and not simply to apply it by rule of thumb.

It is very hard to acquire this knowledge in the ordinary course of events. It is not simply a matter of going back and rubbing up one's physics, as recent advances in our knowledge of atomic physics have brought about so complete a change during the last few years that the majority of us will have to commence to learn the subject *de novo*, and few can afford the time to grapple with the books on the subject written by physicists.

Mr. Souttar, a surgeon and clinician, has written a book on radium that will go a long way to get both the surgeon and the practitioner out of their difficulties. The first half of the book is devoted to the theory and the second half to the practice of radium therapy. There is no sharp dividing line and the author passes by natural stages from the atomic theory in the first chapter to the treatment of carcinoma of the cervix in the last; this blending of theory and practice is one of the outstanding features of the book.

The author has a more profound knowledge of atomic physics and mathematics than the majority of his readers will find it necessary to acquire in order to obtain a practical and useful knowledge of the subject of radium and x-ray therapy, but the early chapters are written in such a way that they will be appreciated by readers of many grades of knowledge, and all medical men should be able to grasp the salient points sufficiently to read the later chapters with a full understanding.

In order not to make the book too bulky it has been necessary to exercise selection in the chapters on the application of radium in different conditions; the subjects chosen are—tumours of the skin, and carcinoma of the tongue and lip, of the breast, of the œsophagus, of the rectum, prostate and bladder, and of the cervix uteri.

It is a book that we can unhesitatingly recommend to the surgeon, to the general practitioner, and to the student.

SEX ETHICS. THE PRINCIPLES AND PRACTICE OF CONTRACEPTION, ABORTION AND STERILIZATION.—By John Ellison, B.A., M.B., B.Ch. (Cantab.), F.R.C.S. (Ed.), F.C.O.G., A. Goodwin, O.B.E., M.D., B.S. (Lond.), F.R.C.S. (Eng.), F.R.C.S. (Ed.), C. D. Read, M.B., Ch.B. (N. Z.), F.R.C.S. (Ed.), F.R.A., C.S., M.C.O.G., and L. C. Rivett, M.A., M.C. (Cantab.), F.R.C.S. (Eng.), M.C.O.G. 1934. Baillière, Tindall and Cox, London. Pp. xl plus 281 with 19 plates. Price, 12s. 6d.

We are in entire agreement with the authors when they say that the time is long overdue for the issue of an authoritative statement on three important questions of the day—contraception, abortion and sterilization. We know what quite a number of sex-starved women think, and we have endless opportunities of reading the compilations of commercially-minded laymen, who have seen in this commendable present-day tendency towards more open discussion of sexual matters an opportunity to make money, and have flooded the market with books that are either unreliable guides or mere repetitions from the writings of pioneers such as Margaret Sanger and Marie Stopes, but we have had very little opportunity of hearing the opinions of leading men in the medical profession on these three important subjects. The extremely conservative attitude that the profession has adopted, particularly over the matter of contraception, is not on the whole likely to enhance its reputation; the medical profession has certainly maintained its dignity and allowed others to make the mistakes, but the fact remains that the attitude its thinking members are now taking, which is well reflected in this very excellent book under review, is in essentials that taken by Marie Stopes a quarter of a century ago, and it is here expressed *authoritatively* for the first time. The word *authoritatively* is, we feel, justified in view of the fact that the four writers are teachers of obstetrics and gynaecology in some of the leading London medical schools.

As the title of the book suggests it is the ethical aspect that has been dealt with primarily, but in the case of each subject there are short chapters on practical methods of choice which will be very useful to the practitioner who is often confused by the multiplicity of the methods that are suggested. The points of view of the Churches—the Anglican, the Roman and the Jewish—are given, explained and discussed. In all three matters Rome appears to take an uncompromising attitude which provides the authors with their opportunity for passing severe strictures on the reactionary tendencies of the Church in general; these are, in our opinion, not always quite fair to the Anglican Church which has shown a much more reasonable attitude, to contraception at any rate. The legal aspect is also discussed and the Law is repeatedly shown to be 'a fool'. For example, there seems to be no legal objection to the sterilization of a woman, but in the case of a man it is under certain—not very clearly-defined—circumstances an indictable offence.

The authors go into the question of extra-marital sexual relations, and in their liberal attitude in this matter they go much further than many will be prepared to accompany them; they suggest that, while there is a surplus female population, unmarried women with strong maternal instincts should be allowed to have children and that if necessary the state should support these. They also give their blessing to temporary 'companionate' marriages: at least, they say, and we quite agree with them, that these are more likely to lead to the final marital happiness than the insoluble marriage ties that some religious codes attempt to enforce.

At the end of each section there is a chapter of 'conclusions'; in these the opinion and advice of the writers are summarized. There are also a number of useful line drawings.

'The medical profession is greatly to blame for its failure to insist on a proper understanding of this subject before men and women enter into the married state, and this omission can be excused only on the grounds that up to a recent date the imparting of sex knowledge was considered indecent by a hypocritical public. That era is dying, and there is no excuse now for any medical practitioner who does not trouble to gain a thorough grasp of the psychology and physiology of sexual intercourse, and impart that knowledge to those who are going to marry'. To those whose conscience pricks them after reading this quotation, we recommend this book; it is not a complete treatise on the subject, but it is a very excellent introduction.

It is unfortunately very seldom that medical writers take the care these writers have taken, over the language in which they express their opinions; even if the subject-matter had not been interesting, the reviewer would have read this book with real pleasure.

L. E. N.

PRINCIPLES IN THE TREATMENT OF INFLAMMATION.—By T. E. Hammond, F.R.C.S. 1934. H. K. Lewis and Company, Limited, London. Pp. xii plus 209. Price, 10s. 6d.

The perusal of this book led to disappointment for in spite of its arresting title it is merely an ill-arranged and carelessly written account of some of the personal experiences and opinions of the author. At times he breaks into generalizations, which in the absence of definite figures, seem to be based on inadequate data.

The book is quite unscientific and all through it runs an undercurrent of contempt for the laboratory worker as opposed to the clinician. The author also appears to imagine that he has a message to deliver to the profession as a whole, and the message is that drugs do not act *per se* on an infecting organism but by altering the body state in some way so that it can overcome the attacks of the parasite. He returns to this theme again and again in his wanderings and accuses most of his colleagues of not recognizing this fact. The only comment on this is that if he is correct he is unfortunate in his professional associates for in the reviewer's experience few medical men nowadays consider a drug acts in the body in the identical manner in which it acts in a test-tube.

The book may be best summed up by quoting a few lines from the concluding chapter. 'Any one who reads this book will be struck by its incompleteness, for so many things are omitted and others are just touched upon. No attempt is made to give a complete account and only certain principles bearing on treatment are outlined. The points dealt with are those that I have pondered over at the bedside of my patients during the last few years. My own fragmentary knowledge is relied upon and little reference is made to the work of others'. We agree entirely with these remarks.

P. A. M.

'ANALAR' STANDARDS FOR LABORATORY CHEMICALS. 1934. Formulated and Issued jointly by The British Drug Houses, Limited, and Hopkin and Williams Limited, London. Pp. xvi plus 295. Price, 3s. 6d. per copy. Postage, 6d.

This is a publication giving an account of nearly 220 inorganic and organic compounds used as laboratory chemicals and as analytical reagents. The maximum limits of the impurities likely to be present, the physical and chemical properties and the tests for finding the limit of the probable impurities are described under each compound. The method of assay is given and some new and delicate tests have also been added. A high standard of purity is insisted upon and the book will thus be of great value not only to analytical chemists who are faced with the problem of finding the nature and extent of impurities present in some of the chemicals used either in

laboratories or in hospitals but also to research workers who look for chemicals of a very high standard of purity.

S. G.

NEW LIVES FOR OLD. HOW TO CURE THE INCURABLE.—By J. E. Barker. 1934. John Murray, London. Pp. xii plus 372. Price, 7s. 6d.

The medical profession is not infallible: it has never claimed infallibility. A patient will sometimes persist in living in the face of a fatal prognosis; this has probably happened at least once in the experience of each one of the 50,000 odd doctors on the British register. Some of these condemned patients have come into contact, or communication, with Mr. Ellis Barker, who has 'treated' them, sometimes through the post, and so Mr. Ellis Barker has written a book about them. There are not many of them, but they are a very distinguished company, as how many of us can claim, as can little Gillian, that our 'case' has occupied three pennyworth of a seven-and-sixpenny book?

We are afraid that Sir Arbuthnot Lane and Sir Herbert Barker, the writers of the first and second introductions, respectively, have snatched the very words from our mouth when they said that the book was 'a very remarkable production indeed'.

FIRST TREATMENTS IN MEDICINE.—By Colonel G. F. Rowcroft, M.R.C.S., L.R.C.P. 1934. Published by the author himself, Culmore, Coonoor, South India. Pp. 69. Price, Re. 1-6

This is a small handbook of 69 pages. According to the author it has been written 'to give the newly launched medical student a certain condensed modicum of diagnosis and treatment'. Going through its pages one cannot help feeling that it is a very poor attempt and will serve no useful purpose. When the author recommends the use of carbolic acid for the treatment of malaria and amœbic dysentery and makes no mention of the efficacy of quinine or emetine, when he recommends grey powder by mouth for treatment of syphilis in all its stages and makes no mention of any of the preparations of arsenic or bismuth, and when he believes that diphtheria can be cured by touching the patches in the throat with pure carbolic and says nothing about the value of antitoxin, one cannot commend the book as a valuable addition to medical literature. The junior members of the medical profession for whose use the book has been written will neither obtain valuable information nor anything that will help them to discharge their duties more efficiently and successfully. On the other hand those who follow some of the recommendations are likely to come to grief and lose both their patients and their reputations.

K. V. K.

STAND UP AND SLIM DOWN (BEING RESTORATION EXERCISES FOR WOMEN WITH CHAPTER ON FOOD SELECTION IN CONSTIPATION AND OBESITY).—By Mrs. E. A. Hornibrook. Sixth Edition. 1934. Williams Heinemann (Medical Books), Limited, London. Pp. xiv plus 167. Illustrated. Price, 6s.

We welcome the appearance of the sixth edition of this small book.

The adjective small is used as a recommendation, for in a surprisingly limited space the author has compressed a remarkable amount of information as to how a woman's health may be benefited by means of simple dietetic precautions and a series of well-thought-out exercises easy to perform and requiring no special apparatus. The book is very clearly written so that it can be understood by any one, and instead of being shown complicated diagrams of the sexual organs readers are referred to standard works on anatomy or physiology if they feel that they need more detailed information than this book provides. This is considered a great recommendation, because

many of the far-too-numerous books on sexual matters that to-day flood the popular medical press contain figures which are not necessary and which (in spite of the statements by their authors who maintain that 'to the pure all things are pure') are calculated to encourage an increased circulation because they excite the ribaldry that is consciously or subconsciously present in a large proportion of the human race.

The book under review although it deals frankly with sexual matters is remarkably free from any suggestion of *double entendre* and is recommended to all women who, as their years advance, are anxious to maintain a pleasing exterior to a healthy body.

DENTAL PROSTHETICS. (OUTLINE OF DENTAL SCIENCE). Volume IV.—By J. D. Logan, L.D.S., F.R.C.S. (Edin.), and W. R. Logan, L.D.S. (Edin.), H.D.D. (Edin.), L.R.C.P. & S. (Edin.). Second Edition. 1934. E. and S. Livingstone, Edinburgh. Pp. xii plus 212. Illustrated. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 6-6

This work which was first published in 1926 has proved so popular that a second edition has been produced. The latest advances in dental prosthetics have been outlined in this edition including recent researches on plaster of Paris and a new chapter on stainless steel has been added.

The book is easily read and the various processes in dental prosthetics are clearly outlined.

One feels inclined to join issue with the authors with regard to their observations regarding certain forms of technique which are almost universally accepted and with which they do not agree. In this respect the volume is definitely an outline of dental prosthetics as taught by them in the Edinburgh Dental School.

Apart from this the work can be recommended to students as an easily readable book which will be a great aid to them in the study of the subject.

H. A. T.

Abstracts from Reports

ANNUAL REPORT OF THE PUBLIC HEALTH COMMISSIONER WITH THE GOVERNMENT OF INDIA FOR 1932

VOLUME I

SECTION II

HISTORY OF CHIEF DISEASES

Chief causes of mortality.—In the report for 1930, it was stated that 'owing to the want of knowledge on the part of those responsible for registration, a number of diseases in which fever is a marked symptom are grouped under the general heading "fevers", whilst the "other causes" group defies any attempt at analysis, although in various limited areas certain efforts have been made which throw a modicum of light on the mysteries concealed by this omnibus term'. This position still holds good; the only diseases for which registration can be said to have reached a fair standard of accuracy are cholera, smallpox and plague, these being the most common and most fatal of the epidemic diseases which periodically devastate India. The urban death rates for smallpox, dysentery and diarrhoea and respiratory diseases were higher than those of rural areas, whilst those for cholera and 'fevers' were lower.

Cholera.—During 1932, recorded deaths from cholera numbered 67,219. The first impression one receives is that this figure is of catastrophic magnitude, nevertheless it is the lowest recorded in India since registration of deaths was introduced and gives a death rate of only 0.2 per mille. The only other comparable

annual figure is that for 1923 when cholera deaths numbered 73,002. As compared with the previous two years, every province showed a large decrease in incidence, although high mortality figures were still registered in the provinces of the United Provinces, Bihar and Orissa, Bengal and Assam. Bengal, the endemic home of the disease, suffered most severely, deaths numbering 33,910, or nearly 50 per cent of the total and the death rate being 0.7 per mille. Assam had a death rate of 0.6, and nearly 10,000 deaths were recorded in each of the provinces of the United Provinces and Bihar and Orissa. In the North West Frontier Province, in the Punjab, in Delhi and in the Central Provinces only mild outbreaks occurred whilst Coorg and Ajmer-Merwara were entirely free. Compared with 1931, only Burma and the Punjab recorded increased death rates and even there the increases were almost negligible.

Plague.—Examination of the figures for plague, over the period of years during which that disease has worked havoc in India, shows that the mortality in 1930 was the lowest on record, total deaths numbering 24,840 with a death rate of 0.1 per mille. This reduction was for the most part due to the fact that in nearly every instance the well-known endemic foci recorded large decreases.

During 1931, an upward trend in the mortality curve was recorded, total deaths numbering 45,626 and the death rate being 0.2 per mille. A further but minor increase occurred in 1932, when deaths totalled 46,504, but the reported cases for the first six months of 1933 indicate that the upward trend of 1931 and 1932 has been checked and that the 1933 total will be well below that for 1932 particularly in the most important foci of infection in Northern India which include the United Provinces and Bihar and Orissa.

Smallpox.—It is an unfortunate fact that India is still the chief endemic focus of smallpox in the whole world. Variola major continues to be the predominant type of the disease and, in consequence, the case mortality runs high although the recorded death rate for the population as a whole is as low as 0.2 per mille.

India seems to have been familiar for many centuries past, both with smallpox and with attempts at its prevention. A short quotation from Dr. Goodall's recently published volume is pertinent in this connection. He writes:—

'At the present day it is recognized that the most efficacious defence against both the epidemic and endemic prevalence of an infectious disease is the immunization of the population against that disease. In the case of one disease, smallpox, the practice known as variolation is of considerable antiquity. Doctors Wong and Wu have shown that it was introduced into China during the eleventh century, and we know that at about the same time it was being recommended, if not actually practised, in Europe. Doctors Wong and Wu are of the opinion that, like smallpox, variolation was introduced into China from India. When it was first practised in the latter country is not known, but tradition refers it to pre-Christian times. It is very probable that India was the primeval home of smallpox and that the disease and its prevention gradually spread eastward and westward from that country'.

Fevers.—A total of 3,456,144 deaths were ascribed to this cause, against 3,956,100 in 1931 and 3,680,165 the decennial mean. Out of this total, 3,272,593 deaths were registered in rural and 183,546 in urban areas, as against 3,761,465 and 194,635 in 1931; and 1,811,648 were males and 1,644,496 females. The death rate was 1.29 per mille as compared with 1.49 the rate both for 1931 and the decennial mean. Ajmer-Merwara again recorded the highest rate of 19 per mille; other high figures were Coorg 18, United Provinces 17, Punjab 16, North West Frontier Province 16, Central Provinces 15, Bihar and Orissa 15 and Bengal 14

Burma 6.2 and Madras Presidency 6.3 as usual returned much the lowest rates.

Malaria.—Nearly 11 million diagnosed cases of malaria were treated in hospitals and dispensaries as compared with about 11½ millions in 1931 and every province with the exception of the North West Frontier Province, Delhi, Bengal and Assam recorded decreases.

Quinine.—At the close of 1932-33 the total Government of India stock of quinine sulphate purchased as such and extracted from Java and Burma barks amounted to 282,759 pounds as against 290,149 pounds in 1931-32. Of this total, 62,634 pounds were at the Indian Museum, 215,513 pounds at Mungpoo and 4,612 pounds at Naduvattam. The total stock of cinchona febrifuge amounted to 22,965 pounds as against 29,953 pounds in 1931-32, including 12,390 pounds at Mungpoo, 10,462 pounds at Naduvattam and 112 pounds at the Alipore Jail.

Quinine from stock amounting to 11,369 pounds was distributed as follows: Punjab 7,768 pounds, United Provinces 1,887 pounds, North West Frontier Province 326 pounds, Central India 504 pounds, Delhi 236 pounds, Baluchistan 92 pounds and Sind 4 pounds. Cinchona febrifuge sold by the Bengal Government on Government of India account amounted to 8,968 pounds.

Dysentery and diarrhoea.—The incidence of these diseases was less than in 1931 and except in the North-West Frontier Province and Ajmer-Merwara, lower mortality rates were recorded throughout British India, the general rate being 0.8 per mille. Of the total, 115,979 deaths were males and 106,825 females; and 176,195 deaths were recorded in rural and 46,609 in urban areas. As usual, the third quarter recorded the highest number of deaths.

Enteric fever.—This disease is no doubt much more prevalent than the statistical records indicate, as most cases are recorded under 'fever'. It is very probable that in large towns like Delhi severe epidemics are of frequent occurrence and as a result a considerable portion of the child population acquires immunity. It is difficult to envisage any rapid improvement in the diagnosis of this disease in rural areas.

Respiratory diseases.—The total number of deaths in British India ascribed to this cause is 405,924 against 420,294 in the previous year.

Tuberculosis.—In previous reports various comments have been made as to the prevalence of tuberculosis in India, but no accurate estimate of its incidence is possible. Assuming that 2 per cent of the total deaths are due to tuberculous disease then nearly 150,000 persons die annually from this infection. But some experts hold that 10 per cent is nearer the truth, and, on that basis, tuberculosis deaths would number 650,000. The latter is almost certainly an exaggerated figure, but it is probable that the actual number of deaths lies somewhere between these two extremes and, even taking the lesser figure, the situation is serious enough.

Evidence clearly demonstrates the higher incidence among women of infection with the tubercle bacillus and the causes for that higher figure are not far to seek. Early marriage, the strain of a rapid succession of pregnancies and periods of lactation and the *pardah* system, with the inherent deprivation of fresh air and exercise which that social system involves, are all factors bound to produce among the younger women of this country a great lowering of resistance to disease which leaves them readily susceptible to acute infections such as tuberculosis. It is not surprising to find that the female mortality rates are much higher than the corresponding male rates in the age groups between 15 and 40 years. Here again recorded figures leave no shadow of doubt. In Bombay city, for example, out of a total of 1,232 deaths from tuberculosis, 761, including 381 males and 380 females, occurred in the age groups 20 to 40 years. During 1931 in Calcutta, three female deaths for every male death were recorded in the age group 10 to 15 years;

two female deaths to one male in the group 15 to 20 years; and 3 females to every male in the group 20 to 30 years.

The only organization solely concerned with anti-tuberculosis work in India is the King George's Thanksgiving (anti-Tuberculosis) Fund. This organization is ill-equipped financially and is mainly concerned with propaganda work. It may as yet be said to have only engaged in preliminary skirmishes with its subtle enemy and it is difficult to see how it can do more until ample funds are provided in every province. But it must be realized that the way to victory does not lie, except in small part, in the provision of clinics, hospitals and sanatoria. Money spent on such institutions will be money largely wasted unless the social factors involved are studied and then attacked with vigour. In the practice of more hygienic methods of living, in the provision of ample and nutritious food supplies and generally in a wider appreciation of the dangers inherent in harmful social practices will be found the way to a gradual decrease of this scourge of civilization and generally to a healthier and happier people.

Ankylostomiasis.—Much the highest number of patients was recorded in Madras Presidency, but this was probably in large part due to the active rural sanitation campaign which was being carried out in that province.

Leprosy.—The total number of cases treated in hospital was 81,083 but warning must once more be given that these numbers give little indication of either the actual or the relative incidence of leprosy in the different provinces.

Rabies and hydrophobia.—The total deaths from this cause were 2,453, only four less than in 1931.

Kala-azar.—The total number of cases treated in hospitals and dispensaries is 105,840, an increase of over 4,500 in the number treated in 1931.

Filariasis.—Under the auspices of the Indian Research Fund Association an investigation into the distribution of filarial infection has been carried out in recent years in Bihar and Orissa. The disease has been found to be prevalent, as 14 per cent of the general population have shown the microfilaria in their blood. The incidence of *F. bancrofti* was found to be the highest in the sea-coast belt, less high in the Gangetic plain and lowest in the submontane arable areas.

Yaws.—*Assam.*—This disease has been found to be widely distributed in the submontane region of the Kamrup district and in the district of Goalpara, Nowgong, Garo Hills, Sylhet, Khasi and Jaintia Hills and the Lushai Hills. Treatment was provided in the districts of Nowgong and Goalpara.

Burma.—In the Mergui district the special survey staff treated 235 cases between April and May and 114 cases in December 1932 and January 1933. As yaws is believed to be very prevalent in the upper reaches of the Tenasserim river, the Mergui district council and the district authorities in Tavoy agreed to extend survey and treatment work to those areas. In Mandalay district, cases were found in the villages of Singu township and arrangements were being made to provide for their treatment. In Lower Chindwin district, it was said to be prevalent in Kani township and sporadic in Yinmabin township. In the Chin Hills, 83 cases were treated in hospitals.

SECTION III

MATERNITY AND CHILD WELFARE

(a) *Maternity work and midwives' training.*—Various attempts recently made to ascertain more accurately the exact cause of maternal deaths have shown that mortality in connection with childbirth is very high and that the problem of maternal deaths is even greater than had been supposed. The lower rate reported for rural areas is probably due to faulty registration, because the facilities for skilled attendance must obviously be lower in the average village even although the general standard of health may be

higher. As in the case of infant mortality, the general causes of this high rate are known, although further investigations in particular localities are required, e.g., into the prevalence of anæmia of pregnancy and its influence on maternal mortality and the occurrence of diseases such as osteomalacia and eclampsia which complicate labour in certain parts of India. Apart, however, from such definite entities, which might be susceptible of rapid improvement, the main causes of maternal mortality lie in social customs which cannot be quickly influenced. Any reform, which has as its *modus operandi* an educational process, is bound to operate only gradually, and this fact should be recognized by hygienists and social reformers alike. This should not be taken as implying that we must be content to allow the reform to proceed at its own rate. It can undoubtedly be hastened and, in particular, by the provision of safe attendance at child birth. That means trained midwives and *dais* in far greater numbers than are at present available. Progress in this matter is exceedingly slow and it is even doubtful if it is keeping pace with the increase of the population. On the other hand, there is undoubtedly a greater appreciation of clean midwifery on the part of the general public. It would be a tragedy if this appreciation were not met by increased facilities in the shape of competent midwives. The training of illiterate women is a tedious business, yet the numbers of even partially educated women who are ready to become midwives is still very small, and the ancient prejudice against work which is regarded as 'unclean' still lingers. On the one hand, those who are trained tend to demand a wage which their education does not justify and, on the other, the family is unwilling to increase its expenditure even when a mother's life hangs in the balance.

Ante-natal work which is such a powerful factor in reducing maternal mortality is certainly on the increase. A greater number of women's hospitals are taking up this work and health visitors are playing their part. The attendance at ante-natal clinics is better than formerly and the public is beginning to understand the need for careful examinations. This is one cheering aspect in a situation which is otherwise far from reassuring.

Child welfare work.—In last year's review, references were made to the reports of the League of Nations' Committee on stillbirths and infant mortality and the hygiene of infants and children of pre-school age. No serious attempts have been made to estimate the causes of the high infant mortality rates in this country. Some of these are obvious and well known; others are obscure. The tendency of the rates to fall, though noticeable, is very small, just as is the case of the general death rate. The low general level of hygiene, the prevalence of preventable disease and the poor state of nutrition of the people all contribute to as high a death rate among children as among adults. A great lowering of the infant mortality rate cannot therefore be expected until the general death rate comes down. There are, however, causes affecting child life specifically which are capable of being attacked and which are as yet receiving very inadequate attention all over India. The amount of child welfare work undertaken is pitifully small and is showing little tendency to increase. Most local bodies are suffering from the economic depression which is affecting the whole world and, since preventive work among children is not regarded as a necessity, it is dispensed with as a luxury. The work of voluntary societies is also being hampered by shortage of funds. At such a time it is all the more necessary to scrutinize carefully all expenditure and it is more than doubtful if this is being done. Frequently a great lack of intelligence is shown in the spending of money and the result is that avoidable waste occurs. Local bodies are satisfied if they give small grants to societies which may have good intentions but are without knowledge. A well trained directing hand is

essential and at least one special officer should be at work under the director of public health in every large province. Unfortunately two out of the three Presidencies have still no such guiding hand, and the consequent lack of co-ordinated effort on behalf of the women and children in Bengal and Bombay is a blot on the public health administration of these provinces. No real advance can indeed be expected without such provision. Were it made, resources could be husbanded and used in constructive effort instead of, as at present is too often the case, wasted on unprofitable forms of charity. The expense of employing such workers is often given as an excuse, but if one province can spare the money, is it not possible for another to do so?

Such child welfare work as is going on at present is almost entirely confined to the towns. The rural areas present a field almost wholly untouched, yet life in the villages is on the whole more advantageous to children than urban life, so that health work has more chance of success there if it could only be initiated. One factor which makes for possibilities in this direction is the advance in road development. This brings the village into touch with larger centres and widens the villagers' horizon. It also renders possible the visits of medical women or health visitors to individual villages or groups of villages. No single village can hope to afford the services of a whole-time worker but one woman resident at a central point could influence a surrounding group of villages. In my opinion this should be the aim in the development of work in rural areas. With this could be combined the co-operation of a number of other agencies such as those alluded to in last year's report.

Depression in trade is also preventing the spread of child welfare work in industrial areas. It is, however, noticeable that business concerns and employers are beginning to realize the fact that care of the health of their employees and their families is an economic proposition. The position in the tea gardens of Assam, for example, is very different now to that in existence some years ago. The jute and cotton mills and the collieries have not as yet given much thought to this problem but there are signs that they too are waking up to the fact that better housing and greater amenities of life make for stable and contented labour. This is certainly the case in the Army where the increased attention paid to the health and welfare of women and children has led to success beyond all expectations.

Health work among women and children needs more and better forms of propaganda than are at present available. The material is poor and badly thought out, and many of the baby and health weeks are little more than 'tamashas'. This is all the more regrettable when one realizes that these could be made real stimulating and educative forces. Voluntary societies who are responsible for a great deal of this work would do well to pay more attention to this aspect of their activities.

A REPORT OF THE SIXTIETH YEAR'S WORK IN INDIA OF THE MISSION TO LEPERS. SEPTEMBER 1933 TO AUGUST 1934

This report concludes the sixtieth year of work of the Mission in India. It describes that the work began originally by those Dublin ladies, the Misses Pym, undertaking to collect between them £30 a year for the relief of lepers. In the first year they collected nearly £600. By the end of sixty years £1,899,372 had been raised, and the Mission is now at work in over twenty lands; and in India alone, still its main field of work, there are now 36 homes of the Mission with 6,700 inmates; 850 healthy children are being rescued by the special provision made for them; aid is given to another 15 homes with 1,600 inmates; 6,000 outpatients attend the Mission's clinics; and an uncounted host of citizens have been served by

the fact that every contagious case cared for has meant diminished risk of infection for them.

The general report is a record of devoted service given by many workers, and a continuous steady expansion of the organization throughout the sixty years of its existence. This is followed by detailed reports from all the homes in India. The Mission is a highly efficient and important organization which is worthy of all the support it can get from the public, for its funds are carefully expended and the greatest possible use made of the money available. The report ends with a brief review by Dr. Muir of the medical work which is fully abstracted below.

A review of the year's medical work.—In looking through the statistics for the last year of the work in India of the Mission to Lepers, we find that many of the figures remain about the same as in the previous year. But the number now under treatment has increased by 665, or over 10 per cent. Also the outpatients under treatment have increased by 1,722, or over 58 per cent; and those who have improved under treatment are 54 per cent more than last year. In fact the outpatients are rapidly increasing and will soon at the present rate exceed the inpatients under treatment.

The popularity of treatment is a striking feature of these leper homes. When it is remembered that several years are often necessary before recovery can take place, this is the more remarkable. Another remarkable thing is that almost all this increasing inpatient and outpatient treatment has been done by practically the same medical and nursing staff as was previously employed, though doubtless much extra help is given by educated and trained patients. At the back of all this increased work are two things: sympathy and enthusiasm; and it is these that make the medical work of the Mission so popular and such a success.

I referred last year to the importance of children, and the splendid work that the Mission does in its many homes for the children of leprous parents. During the past year, the children problem has been emphasized more and more by workers all over the world. It has been shown that the age factor is one of the most vital in the spread of the disease. In early years resistance to leprosy is much lower than in adult life. Thus the infection enters and spreads through the bodies of young children, many of whom become the infectious cases of the next generation; whereas those infected after puberty become chiefly non-infectious cases. If all children under ten years of age could be effectively isolated from infectious cases of leprosy, the disease would, in all probability, become a negligible one within two generations; but that is a very large IF. The Mission to Lepers has so far led the way in 'Save the children' policy; and will, I believe, realizing the all-importance of this side of the problem, develop more and more their splendid children's homes.

Apart from the work which the Mission itself is doing, it is inciting others who share its spirit to undertake anti-leprosy work. As an example may be mentioned an ex-patient who is running three leprosy clinics in a highly endemic area, where no fewer than 125 patients are cared for every week.

SOME OBSERVATIONS ON DYSENTERY AND DIARRHŒA AT DARJEELING

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—At Darjeeling there is a considerable increase in the incidence of dysentery and diarrhœa during the rains, but there is no indication of any epidemic.

The ideal hypnotic should have a wide margin of safety, so that there is little likelihood of dangerous overdosage even if the advocated dose is exceeded; it should of course have no serious adverse effect on the important organs of the body, such as the heart, that is to say, it should be entirely non-toxic in its ordinary effective dosage; further, it should produce no unpleasant effects, either at the time it is given or afterwards when its hypnotic effects wear off; and, finally, it should act rapidly.

Ortal is said to possess all these qualities.

It is indicated in insomnia, nervous excitement, migraine, acute alcoholism, and as a premedicant when a general anaesthetic is to be given. It is not, however, an analgesic and therefore if an analgesic as well as an anaesthetic effect is desired, some such substance as aspirin should be administered with it.

A TEACHING STETHOSCOPE

By WILLIAM EVANS, M.D.

THE stethoscope illustrated here consists of a scientifically constructed sound chamber which incorporates a diaphragm and tension wire designed to transmit heart sounds which are mostly within the bass range of piano notes. Although the intensity of the sounds is diminished to some extent, the quality is preserved

and is comparable to that which a student hears when using his own binaural stethoscope.

Six observers (the instructor and five students) may auscultate the chest at the same time, and in this way the teacher is able to emphasize certain characteristics as they occur. It thus aids the instruction of students in the first principles of auscultation applied to both normal and adventitious heart and breath sounds, and

it provides the means of knowing that the student has heard the particular abnormality to which his attention has been drawn by his teacher. The stethoscope also enables every student among a moderately

large class to elicit a particular auscultatory sign in an ill patient without causing discomfort involved by repeated individual examination.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

THE INCIDENCE OF PNEUMOCOCCAL TYPES IN PNEUMONIA IN ASSAM

By L. EVERARD NAPIER, M.R.C.S., L.R.C.P.

and

DHARMENDRA, M.B., B.S.

From the Calcutta School of Tropical Medicine

PNEUMONIA has been reported as an important cause of death amongst the labour forces employed on tea estates in Assam. It was thought that, before undertaking any extensive enquiry into the incidence and cause of this disease, it would be as well to carry out a preliminary investigation into the bacteriology of the disease as it occurs in Assam, in order to find out if the infection were mainly pneumococcal, and if so what were the serological types of pneumococci mainly responsible.

Previous work on pneumococcal types

A considerable amount of work has been done on this subject during the last 25 years and figures showing the prevailing types in a number of places in Europe, America and Africa have been obtained. It will not be profitable to review these at any great length here, but two series are given for purposes of comparison:—

He did not make high-titre sera for any of his group IV strains, but used the serum of nine patients taken within one or two days of the crisis and put these up against 32 of his group IV strains. Two of his samples of serum each agglutinated the same six strains; the remainder agglutinated only the homologous strain. This suggests that there was a common local strain, which was not type I, II, or III.

Cunningham, Cruickshank and Ramakrishnan (1925) isolated 40 strains from cases of pneumonia in Madras; of these 29 were bile-soluble and were found to belong to the types as shown below:—

	Number	Percentages
Type I ..	18	62.06
" II ..	3	10.7
" III ..	2	7.2
Group IV ..	6	21.4

The striking point about these workers' observations is the small number of strains of group IV, compared with Malone's and our findings (*v. i.*). Few details are given of the bacteriological methods of identification, but bile-solubility appears to have been taken as the final criterion for differentiating *Streptococcus pneumoniae* from other streptococci. We do not think that this criterion is now accepted as absolute, and, though we have used the bile-solubility test in every case, we have classed four non-soluble strains as *Str. pneumoniae*, as they exhibited the diplococcal form in the mouse's heart's blood; of these four strains one

TABLE I

	CECIL AND PLUMMER (1933) NEW YORK		GLYNN AND DIGBY (1923)		
	LOBAR PNEUMONIA		LOBAR PNEUMONIA		BRONCHO-PNEUMONIA
	Number	Percentages	Number	Percentages	Number
Type I ..	1,384	32.1	47	44.8	1
" II ..	991	23.0	22	20.9	4
" IIA	1	0.9	1
" III ..	477	11.1	2	1.9	..
Group IV ..	1,458	33.8	33	31.5	16
Number in series	4,310		105		22

It is a subject that has not been taken up to any great extent in India, but Malone (1924) typed 106 strains of pneumococci isolated from cases of pneumonia occurring in Waziristan and Baluchistan. The incidence of the different types was as follows:—

	Number	Percentages
Type I ..	30	28.3
" II ..	18	17
" III ..	8	7.5
Group IV ..	50	47.2

was found to agglutinate with our serum A and one with our serum B.

It seems possible that some at least of these 11 strains should have been included in group IV. Had they all been included in group IV, the percentage incidence in this group would have been brought up to 42.5 which is much more in keeping with Malone's and our findings.

Previous work on pneumococcal types by one of the writers.—One of us (D.) working with Lieutenant-Colonel H. W. Acton typed 55

strains obtained from pneumonia cases in Calcutta; the results were as follows:—

	Broncho	Lobar	Total	Percentages
Type I	.. 4	7	11	20.00
" II	.. 1	2	3	5.45
" III	3	3	5.45
Group IV	.. 19	19	38	69.09
	24	31	55	

The incidence of group IV in this series is much higher than in either of the other Indian series, themselves higher than the British or American series, but the Calcutta series were mixed cases, both lobar and broncho-pneumonia. However, if the broncho-pneumonia cases are excluded the incidence of group IV is still over 60 per cent.

The group IV strains of this series were further differentiated by testing them with type sera supplied by Dr. Georgia Cooper from New York; the results were as follows:—

	Broncho	Lobar	Total
Type 4	.. 1	..	1
" 5	.. 1	..	1
" 6	.. 4	4	8
" 11	.. 1	..	1
" 13	.. 3	..	3
" 14	.. 2	..	2
Ungrouped	.. 7	15	22
	19	19	38

The present investigation

In order to investigate the pneumococcal types in Assam a laboratory was established at Cinnamara, near Jorehaut; the reasons for the choice of this locality were that it was centrally situated with a large number of gardens within easy reach, and that suitable rooms for a laboratory and for animal accommodation were available. The locality exhibits no special features, that is to say it is a fairly typical example of the tea districts in the plains of Assam.

The medical officers in the neighbourhood were notified and asked to send in specimens of sputum from pneumonia cases. They were supplied with sterilized sputum bottles; details regarding the methods of collecting sputa were sent out with the sputum bottles; and it was requested that the specimens should only be collected personally by the assistant medical officers. Most of the specimens received were satisfactory, but a number were discarded as containing saliva only.

The method of procedure was as follows:—

On receipt of the specimen it was poured into a sterile Petri dish and a suitable sample of purulent exudate picked up with a platinum needle and inoculated on to a blood-agar plate and at the same time smears were made on three slides, which were subsequently stained

by Gram's method, by the Ziehl-Neelsen, and by Hiss's method for staining the capsule, respectively.

Another sample was tested by Armstrong's (1932) method on a slide against the 'fixed' types I, II and III.

With an emulsion from the sputum the precipitin test, suggested by Oliver (1920), was also carried out against the three 'fixed'-type sera.

Finally, a mouse was injected intraperitoneally with an emulsion from the sputum.

Results obtained with the direct typing methods

Armstrong's method consists in mixing a sample of sputum with about four times its volume of each type of the three 'fixed'-type sera, and examining the mixture under the microscope immediately; a positive result is indicated by a marked swelling of the capsule of the diplococcus so that in some instances it reaches almost the size of a red cell, whereas with the other sera no change takes place. This was done in 45 instances and three positive results were obtained; in each of these, confirmation of the correctness of the result was obtained by the mouse-inoculation method described below. No false positives were obtained, but in three instances negative results were obtained by Armstrong's method with sputa from which pneumococci of one of these three 'fixed' types were isolated.

Oliver's method was used in 14 instances, but no positive results were obtained, and later it was given up altogether.

Mouse-inoculation method.—On the morning following the inoculation, if the mouse was not dead, it was killed and a culture taken from its heart's blood on to blood agar and into broth. A smear was also made directly from the heart's blood and this was stained and examined. The blood-agar plates and the broth tubes were incubated at 37°C. for 24 hours. If both the blood-agar plate and the broth tubes showed a pure culture of pneumococcus, one broth tube was put aside for the bile-solubility and sugar tests, and the others were used for the agglutination tests; the contents were transferred to a sterile centrifuge tube and centrifuged; the supernatant fluid was rejected and the deposit suspended in normal saline; the saline suspension was used for the agglutination tests with the three 'fixed'-type high-titre sera and the 28 sera (classed as group IV) obtained from Dr. G. Cooper (we had no serum for type 26). Both the microscopic and the macroscopic methods of agglutination were used. For the former a thick emulsion of pneumococci (about 2,000 million per c.cm.) was mixed with a one-in-ten dilution of the 31 different sera and the slide examined after about half an hour in the 37°C. incubator; and for the latter an emulsion containing about

1,000 million organisms to the c.cm. was mixed with equal parts of a 1-in-5 dilution of each serum, placed in a water-bath at 55°C., examined after 2 hours, and then again after 20 hours.

The immediate test with peritoneal washings

Although the agglutination with the culture made from the hearts' blood of the mice was used as the final criterion for diagnosing the type, the immediate method of testing with the peritoneal exudate was also carried out in most instances.

The peritoneal cavity was washed out with about 2 c.cm. of normal saline, and if there was little cellular exudate an agglutination test was carried out with types I, II and III sera, and usually about 9 or 10 of the other type sera, as circumstances allowed. If there was much cellular exudate the agglutination test was not done, but the fluid was centrifuged and the supernatant fluid used for a precipitin test against the type sera.

Results.—The agglutination test was done on 26 occasions; it was positive in six and doubtful in two; in all eight cases the organism was proved by the confirmatory tests to be of the type indicated. In the other 18 cases, the organisms did not belong to any of the strains against which it had been tested.

The precipitin test was done on 23 occasions; it was positive in three cases and 'doubtful' in two; in all five the organism was shown to be of the type indicated. In the 18 remaining cases the test was negative, but in only one of these was the organism found to belong to a type against which it had been tested; it was tested by the precipitin test against types I to III and 4 to 12 with negative results and was eventually shown to belong to type 11.

Thus, taking two immediate testing methods together, we see that out of 14 occasions on which a positive result should have been obtained, there were 9 positive results, 4 doubtful and one negative. There were no false positive results, nor was there even a doubtful result in a case in which a negative one should have been given.

Results

Sixty strains were identified as *Str. pneumoniae*; the remaining five strains were hæmolytic streptococci, on which no further work was done.

The final results of the 'typing' of the 60 pneumococcal strains are shown in table II below.

It will be seen from this table that 8 were agglutinated by one or other of the three 'fixed'-type sera and 24 by the American types 4 to 32; this left 28 strains unidentified.

In order to classify these it was necessary to make high-titre sera; we decided to make sera from four strains in the first place.

* The fate of one case of type I, of one case of type A and of three cases of type B was not recorded.

Preparation of high-titre serum.—Adult rabbits were used for this. The virulence of the strains was first raised by passage through a series of mice. The criterion for virulence was that one-millionth of a cubic centimetre of a broth culture would kill a mouse within 36 hours; 13, 12, 8 and 8 passages, respectively, were necessary in the case of the four strains.

An emulsion was made in saline from the centrifuged deposit from a broth culture inoculated 20 hours earlier from the heart's blood of a mouse. For the first three series of inoculations cultures killed by heating to 60°C. for half an hour were given, and then, after the resistance had been thus raised, live cultures were used. The injections were given intravenously into the ear of the rabbit. Eight courses of injections, each consisting of three injections on consecutive days, were given; an interval of from 5 to 7 days was allowed between each course, the whole procedure thus taking about ten weeks. The doses given were as shown below:—

Course	Amounts of broth in c.cm. from which deposit was obtained	Saline emulsion
1st	1, 2, and 3	Killed
2nd	5, 5, and 7.5	"
3rd	10, 15, and 15	"
4th	1, 2, and 3	Living
5th	5, 5, and 7.5	"
6th and 7th	10, 10, and 10	"
8th	15, 15, and 20	"

The blood was taken five days after the last injection in each case and the serum separated. A serum with a titre of 1 in 160 for the homologous strain was obtained. Cross-agglutination tests showed that these four sera represented two different types; these we have provisionally named A and B. Of the 28 unclassified strains 8 were agglutinated by our type A serum, and 14 by our type B. Cross-agglutination tests with the other types of pneumococci showed that serum A agglutinated type I cocci definitely but not completely in a dilution of 1 in 20, and types 7 and 20 partially in a dilution of 1 in 10 and 1 in 20, respectively, so it is apparent that there is some antigenic relationship between our type A coecus and these types, though type A coecus is not agglutinated by their high-titre sera.

There did not appear to be any relationship between our type B serum and any of the other types isolated.

Clinical types and death rate.—In a few cases we were able to confirm the clinical diagnosis ourselves, but in the majority we accepted the diagnosis of the medical officer in charge of the case, and in no case had we any reason to doubt the accuracy of the clinical diagnosis. Only 45 of the cases were lobar pneumonia; the remainder were broncho-pneumonia.

Amongst the broncho-pneumonia cases there was only one death in 15 cases, but amongst the lobar pneumonia cases there were 7 deaths out of 40 cases in which the clinical results were known (of the fate of 5 patients we had no information), that is to say, there was a death rate of 17.5 per cent, which in a series of which only 4 out of 45 were under twenty years of age is low, in view of the fact that none of the patients were treated with specific serum. There was one death amongst the three type I lobar pneumonia cases whose fate was known, no deaths amongst five type A cases, and three deaths amongst seven type B cases. The figures are too small to allow of any dogmatic conclusions, but they do suggest at least that the local type B is a comparatively virulent organism.

Many figures are available to show the relative virulence of the different types; we will quote three series, two from America and one from Great Britain.

Osler and McCrae (1925), Cecil and Plummer (1933), and Ferguson and Lovell (1928) give the mortality percentages with the different types, as shown below:—

	Osler and McCrae	Cecil and Plummer	Ferguson and Lovell
Type I	.. 24.1	28.2	26
" II	.. 37.7	48.9	20
" III	.. 53.7	42.7	*
Group IV	.. 22.2	31.3	26.4

* Insufficient figures available.

Pneumococci in normal throats

Pneumococci can be recovered from the upper respiratory passages in a large percentage of persons examined. Except however in the presence of an epidemic, or when the persons examined have been in close contact with a case or cases of pneumonia, the more virulent types are not usually found. There are many records of examinations of non-pneumonia cases reported in the literature; three examples are given here.

Thomson and Thomson (1932) found pneumococci in 67 out of 103 adenoids from children. Sailer, Hall, Wilson and McCoy (1919) collected 111 strains from 700 soldiers who had been more or less contacts in a pneumonia epidemic, and Avery *et al.* (1917) reported 121 strains from the throats of 297 normal persons; the distribution amongst the types is shown below:—

	Sailer <i>et al.</i>	Thomson Thomson	Avery <i>et al.</i>
Type I	.. 5.4	0	0.8
" II	.. 13.50	2	0
" IIA	18.2
" III	.. 4.5	13	28.1
Group IV	.. 76.6	85	52.9
Number in series	.. 111	67	121

We collected only 12 strains from 25 normal throats; on the basis of the above classification they could all have been put into group IV, differentiating them further, however, we were able to place six of them into definite groups, as shown below:—

Type 4 2
" 18 1
" A 1
" B 2
Unidentified 6

Discussion.—The first point that strikes one is that in the three Indian series, the Frontier series (Malone), the Calcutta series, and the Assam series, the incidence of pneumococci of group IV, as compared with the findings in England and America, is very high, and that it is highest in the present series. The distribution amongst the types in our series is, in fact, far more like the distribution that one finds in a series of strains collected from cases of broncho-pneumonia. The second point is that the reported death rate in our series is distinctly low; this is particularly striking as all the patients were tea-garden coolies treated in the garden hospitals where nursing, as it is understood in modern hospitals in Europe and America, and even in our large cities in India, is unknown. Though in a few instances mistakes in the clinical diagnosis may have been made, we cannot question the fact that the great majority of the cases diagnosed as lobar pneumonia had pneumonia of a definitely lobar type, but it is still possible that this pneumonia does differ from lobar pneumonia as it is encountered in England, in its pathology as well as in its bacteriology. (It was never possible to obtain post-mortem examinations in these cases.)

However, it is clear from our bacteriological findings that, whatever the clinical type of pneumonia, the fixed types I and II, which are the types used in the preparation of therapeutic serum, are comparatively rare, and that there is more than an eight-to-one chance against serum being of any value at all in the treatment of pneumonia in this district.

Regarding the two local types A and B, there are certain observations that appear to be contradictory; for example, these two types were found in 6 out of the 15 cases of broncho-pneumonia and 3 out of the 12 strains isolated from normal throats, but on the other hand of the 7 lobar pneumonia patients from whom type B was isolated and whose fate was known three died.

The other type (A) was responsible for no deaths at all, as far as we know, though it was isolated from 5 lobar pneumonia cases whose fate was known.

Further, our laboratory experiences suggest that the toxicity of type B is definitely higher than that of type A, for, whereas with the two strains of type A 13 and 12 passages respectively were required to raise their toxicity to the level where one-millionth of a cubic centimetre of broth culture kills a mouse in 36 hours, only 8 passages were required in the case of the two strains belonging to type B.

We have an analogy in type III; in America this organism is frequently found as a harmless commensal in the throats of healthy persons, yet type III pneumonia appears to be a very fatal infection.

The evidence on the whole seems to be in favour of type B being a strain with virulent potentialities; there is also evidence that it is a widespread one in the locality.

Summary and conclusions

The sputa from 65 cases of pneumonia were investigated with reference to the species and type of streptococcus that predominated.

Direct typing, mouse inoculation and cultural methods were used.

Five strains were identified as hæmolytic streptococci and 60 strains as pneumococci. Of the 60 pneumococcal pneumonias 15 were broncho-pneumonia and 45 lobar.

Of these 60 strains, 8 belonged to the 'fixed' types, 24 to other American types, and 28 were not identifiable with any sera we had in our possession; by the preparation of high-titre sera, 22 of the unidentified group were shown to belong to one of two types; these we have provisionally called A and B.

Our type A was not associated with any mortality and appears not to be a virulent type. Type B was responsible for three deaths in 7 cases of lobar pneumonia whose fate was known; on the other hand 4 out of the 15 strains from

PRELIMINARY OBSERVATIONS ON A NEW SOLUBLE ATEBRIN COMPOUND

By JOHN R. BLAZE, M.D. (Lond.), M.R.C.P. (Lond.)
Physician, General Hospital, Colombo
and

A. T. W. SIMEONS, M.D. (Heidelberg)

The following is a preliminary report on 21 cases of malaria treated with atebirin musonate, an atebirin salt of musonic acid, which was placed at our disposal by the manufacturers (Bayer-Meister Lucius) for a clinical trial during the epidemic in Ceylon.

Atebrin musonate is a yellow powder, readily soluble in water; it is supplied in dry ampoules,

(Continued from previous column)

cases of broncho-pneumonia and 3 out of 12 strains from normal throats were type B.

It is evident that there is little 'fixed'-type pneumonia in this district and therefore commercial therapeutic serum is not likely to be of much use in treatment.

It is considered that type B is probably a strain with virulent potentialities that has a widespread distribution in the area in which we were working.

If further experience shows that our type B pneumococcus is common in other districts in Assam and in other years, the question of making serum against or vaccines from this organism should be considered.

Acknowledgments

Our thanks are due to Dr. D. Manson, medical officer of the Jorehaut Tea Company, for placing a laboratory at our disposal and for much assistance in connection with this enquiry; also, to Dr. D. Manson, Dr. G. Macdonald, and to other medical officers who kindly sent us sputum from their pneumonia cases. The high-titre sera used in this enquiry were kindly supplied to us by Dr. G. Cooper, Health Department, New York.

each containing 0.125 gramme (corresponding to 0.1 gramme of atebirin dihydrochloride), which is to be dissolved in exactly 3 c.cm. of water, for intramuscular or intravenous injection. The dose suggested by the manufacturers is 1 to 3 ampoules for intramuscular, and 1 ampoule for intravenous administration.

Before going into the case-histories it may be worth while to consider a few theoretical points.* Hecht (1933) has shown that a large portion of atebirin taken by the mouth is retained in the upper intestine, liver and bile, and concluded from his observations that the atebirin circulates from the intestine to the liver, is excreted with the bile back into the duodenum from where it is again reabsorbed into the liver. It is believed to circulate in these organs in this way before reaching the peripheral blood in any large amount. If this is correct it is probable that upon continued administration a point is reached where the liver becomes saturated with atebirin, and the atebirin then 'overflows', so to speak, into the peripheral circulation, where it acts as a parasiteicide. This might explain the fact that atebirin given orally has no immediate effect upon the clinical picture. Parasites and fever remain uninfluenced during the first 3 days of oral atebirin treatment; while usually on the fourth day there is an abrupt change, in that the temperature drops to normal and remains there, the parasites suddenly decrease or disappear, and a considerable amount of atebirin, hitherto practically absent, appears in the urine (Tropp and Weise, 1933). This would indicate that only about the last 6 to 7 tablets of a 15-tablet course of atebirin are actually therapeutically utilized whereas the first 9 tablets are necessary to saturate the liver to such an extent that it will allow the subsequent doses to leak out into the general blood stream.

If these conjectures are anywhere near the truth an immediate effect might be expected from parenterally administered atebirin, both on the parasites and on the fever; the necessity of saturating the liver with the drug before it can act on the parasites should be avoided; and a therapeutic effect equivalent to that of 15 tablets by the mouth should be obtained with a far smaller quantity of atebirin given parenterally. R. Green (1934), studying the toxic effects of atebirin, has already discussed Hecht's theory of 'inner circulation' and hints at similar conclusions. He also finds that toxic effects, such as headache, yellow discoloration of the skin, and colicky pain in the upper abdomen, are seen in cases where the appearance of atebirin in the urine, usually on the third or fourth day, is delayed. This can mean two things: either that toxic symptoms are caused by an exceptionally high concentration

in the upper intestine and liver, or that after a high concentration in these organs has been reached, toxic symptoms are caused by the liver suddenly spilling an unusually large quantity of atebirin into the peripheral circulation. We are inclined to believe that the first explanation can account for headache and colicky pain, while the second causes yellow discoloration of the skin. Our reasons for this belief are conclusions drawn from the present series. In none of our cases did we observe either colicky pain or headache; and a yellow discoloration was only (and that very markedly) noticed in 2 cases which had received an intravenous injection of atebirin musonate. It seems as if a sudden high concentration of atebirin in the peripheral blood causes the drug to be deposited in the skin. From the appearance of the urine it may be inferred that excretion begins within a few hours after intramuscular injection of atebirin musonate.

In the present series we are chiefly concerned with the clinical treatment of malaria. During an epidemic and in a congested hospital it becomes exceedingly difficult to follow up the cases; the question of relapses will therefore be reserved for a future publication. We have excluded from the present series cases suffering from other diseases in addition to malaria, of which a number were treated with the same results as far as the malaria was concerned.

*Case 1 (chart 1).—*An adult male, admitted with a history of 1 month's fever with chills, claimed to have had no previous treatment. Blood: B. T. +++ (30 to 40 parasites per field, thin film). One intramuscular injection of 3 ampoules (0.375 gramme) of atebirin musonate; no other treatment. The following day maximum temperature was 100°F. (4-hourly reading). Marked decrease in number of parasites; second and similar injection given. On the third day temperature normal, blood film and thick drop both negative; third and last injection given. The patient received no other treatment and has remained free from fever and parasites while under observation. In this and all subsequent cases the injection proved to be painless; no local irritation or reaction was seen in any cases of this series.

*Case 2.—*An adult male suffering from fever and chills for 3 days. Blood: fair number of M. T. rings. Three ampoules of atebirin musonate given in one injection. The temperature dropped to normal within 4 hours and remained so during the period of observation. On the second day the thick drop showed scanty rings; a second injection was given. On the third day an occasional ring was found in the thick drop, 3 atebirin tablets were given by the mouth, and repeated on the next 2 days. On the fourth day the blood was free from parasites, and remained so on every following examination. The patient was carefully questioned, and no untoward symptoms observed.

*Case 3.—*A heavy mixed infection with M. T. and B. T., the latter preponderating, in an adult male suffering from fever with rigors for the last 12 days. After the first injection, M. T. negative, B. T. ++. After the second injection (third day), M. T. negative, B. T. scanty, temperature normal; three days' oral atebirin after-treatment started. From the fourth day onwards the blood has remained free from parasites. No untoward symptoms.

*Case 4.—*An adult male, suffering from fever with rigors for 4 days; no previous treatment. Blood:

Charts showing effect of atebrin musonate on the temperature and parasitic infection.
(The arrows indicate the injection of 0.375 gramme of atebrin musonate)

B. T. +, M. T. +. An injection of atebtrin musonate was given and followed by 4 days of oral atebtrin, 1 tablet thrice daily. Apart from the fact that the second rise in temperature remained comparatively low the chart shows no improvement on an ordinary oral atebtrin chart. The blood was not examined on the third and fourth days, but found to be negative on the fifth day, and has remained negative while under observation.

Case 5.—An adult male suffering from fever with rigors for 3 days. Blood: B. T. +. One injection was given without any after-treatment. The blood was free from parasites on the day after the injection and the temperature normal, and remaining so for the period of observation (seven days).

Case 6.—An adult male with a mixed M. T. and B. T. infection. One injection of atebtrin musonate given; no after-treatment. Temperature normal within 8 hours. M. T. rings negative, on the third day; B. T. persisting for 4 days. Temperature remained normal from the second day onwards.

Case 7.—An elderly male suffering for 3 days from fever. The blood showed a very heavy M. T. infection, rings ++, crescents ++. One injection was given which reduced the number of rings considerably, the crescents persisting. As both temperature and parasites persisted two further injections on the fifth and sixth days were given with an immediate effect on the temperature, the parasites disappearing on the eighth day (second day after last injection). The crescents remained uninfluenced throughout.

Case 8.—An adult male suffering for 8 days past from high fever with rigors. Blood: B. T. +. He was given one injection and the blood was found free from parasites 2 days later. The patient left the hospital on the fourth day feeling well. While the time of observation is too short to form an opinion regarding a recrudescence the case has been included as an example of the effect on the clinical picture sometimes seen after a single injection.

Case 9.—An elderly male suffering for one month from fever and chills. Blood: M. T. rings +. One injection brought the temperature gradually down to normal in 4 days. The rings persisted and on the sixth day crescents appeared for the first time. On the ninth day there was a recrudescence of the fever. An injection was given followed by another the next day. The temperature fell, and the rings disappeared for the first time. Crescents persisted throughout.

Case 10.—An adult male suffering from fever for the last 3 weeks and claiming to have had no previous treatment was found to be heavily infected with M. T. rings. One injection only reduced the number of parasites, while the fever persisted. Two other injections were therefore given on the fifth and sixth days. On the seventh day the temperature became normal and the blood free from rings, remaining so during the period of observation. Crescents appeared on the fourth day and persisted throughout.

Case 11.—An elderly male suffering from fever with chills for the last 4 weeks was admitted unconscious with a very bad pulse. B. T. parasites were found in the blood and an injection of atebtrin musonate given at the height of the fever. The temperature dropped within a few hours and remained normal, the parasites disappearing on the second day after injection. Parasites reappeared on the twelfth day, without any rise in temperature; after another injection the blood was again free.

Case 12.—An adult male suffering from fever and chills for 3 days. Blood: B. T. +. One injection caused parasites and fever to disappear in 24 hours. On the ninth day however the temperature rose with a rigor from normal to 104°F. and the blood was found to contain M. T. rings and crescents. Injections were given on the tenth and the eleventh days with an immediate effect on temperature and parasites. No crescents were detected after the eleventh day.

Case 13.—An adult male suffering from a mild M. T. infection was kept under observation without any treatment for 2 days and injected on the third. On the fourth day temperature was normal and parasites absent. On the fifth day a few rings reappeared and a second injection was given. Parasites remained absent on the two following days. The patient could not be induced to remain in hospital; but he has reported regularly for 18 days in all during which time the temperature has remained normal and the blood free from parasites.

Case 14.—A young male patient suffering from a heavy B. T. infection. Two injections were given at an interval of about 15 hours. On the day of the second injection the blood was free from parasites and the temperature almost normal. On the seventh day a few parasites reappeared in the blood. As they were still present on the eighth day, another injection was given, although there was no rise in temperature; during the 3 following days of observation the parasites remained absent.

Case 15.—An adult male suffering from an M. T. infection. Two injections were given at an interval of 24 hours. On the day after the second injection the temperature became and remained normal, the rings disappearing on the fifth day. On the eighth day a few rings were again seen. They however disappeared on the following day without any treatment and remained absent for the period of observation (16 days, 4 days longer than chart 15), the temperature remaining normal.

Case 16.—A heavy M. T. infection in an adult male was treated with 2 injections. Although the period of observation is too short to form an opinion regarding a recrudescence, the case has been included because it is the only one in which a high temperature was seen after the second injection.

Case 17.—An M. T. infection in an adult male. The patient was kept under observation for 2 days without any treatment and given an injection on the third and fourth days. The temperature dropped and remained normal after the first injection, the rings persisting for 1 day after the second injection. On the ninth and tenth days of observation a few rings reappeared without any febrile reaction and disappeared spontaneously, the blood remaining free up to the time when the patient was discharged, 7 days later.

Case 18.—An adult male suffering from an M. T. infection was observed without treatment for 2 days and given injections on the third and fifth days. On the sixth day maximum temperature was 99°F.; from then on normal. On the fifth day rings were absent, while crescents appeared, this remaining so during the period of observation.

Case 19.—A young male patient having a fair number of M. T. rings in his blood was kept under observation without any treatment for 1 day and received an injection on the second and third days. On the fourth day the temperature became and remained normal while from the sixth day onwards rings were absent and crescents present.

Case 20.—A young male suffering from a very heavy M. T. infection with rings and crescents, having received no previous treatment, was given an intravenous injection of 1 ampoule of atebtrin musonate (0.125 gramme). The injection was not followed by any untoward symptoms, but on the next day the temperature rose to 105°F. and a marked yellow discoloration of the skin was noticed. An intramuscular injection of 0.375 gramme of atebtrin musonate was given at the height of the fever. On the following day the temperature was normal and blood free from parasites. Crescents, not seen on the second, third and fourth days, reappeared and persisted from the fifth day onwards. On the seventh day there was a rise in temperature (99°F.), but the blood remained free from rings even after a provocative injection of adrenalin, and 2 days later the temperature returned to normal without any treatment.

Case 21.—A young male patient suffering from an M. T. infection was given an intravenous injection of 1 ampoule of atebirin musonate (0.125 gramme). On the next day the temperature was still 104°F., and a yellow discoloration of the skin was distinctly noticeable. An intramuscular injection of 3 ampoules was given. From the fourth day onwards temperature was normal, and from the fifth day parasites were absent from the blood.

Conclusions

The conclusions that can be drawn from this short series of cases are :

(1) The intramuscular injection of atebirin musonate in therapeutic doses does not give rise to toxic or unpleasant symptoms.

(2) While a single injection of 0.375 gramme of atebirin musonate has in some cases a remarkable effect on the clinical picture, a recrudescence usually occurs within a few days. Heavy malignant tertian infections are only slightly influenced.

(3) Two injections of 0.375 gramme given on successive days are sufficient to control within 48 hours the temperature, and in a maximum of 4 days all forms of benign tertian parasites, and the ring forms of malignant tertian. Crescents appear to be in no way influenced, and must be destroyed by plasmochin. In some cases there is a reappearance of parasites in the blood after a few days, but they disappear spontaneously. In no case hitherto observed has there been a return of fever after 2 injections. We are dealing with unusually heavy infections in a poor and mostly underfed class of patients.

(4) The intravenous route though harmless is not satisfactory for routine treatment.

(5) The theoretical considerations already set out are supported by the result obtained. Atebrin musonate is a drug worthy of further investigation.

(6) The immediate results of treatment with atebirin musonate appeared to be good enough to justify our making this preliminary report. But the period of observation has not been long enough to enable us to compare the relapse rate after atebirin musonate with that after oral atebirin or quinine. Observations upon this important question are being made.

Our thanks are due to the Director of Medical and Sanitary Services, Dr. Briercliffe, for permission to try this drug; and to the Medical Superintendent and the other members of the staff of the General Hospital, Colombo, for their help and co-operation during a time of quite unusual congestion and overwork due to the prevailing epidemic.

HABITUAL USE OF BARBITURIC ACID DERIVATIVES IN INDIA

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)
 LIEUTENANT-COLONEL, I.M.S.

and

G. S. CHOPRA, M.B., B.S.

(Drug Addiction Enquiry, Indian Research Fund Association. Series No. 22).

Introduction.—During recent years a large number of barbituric acid derivatives have been introduced into therapeutics; the following are some of the important compounds known to the profession in this country :—

- (1) Barbitone, or veronal (di-ethyl-barbituric acid),
- (2) sodium barbitone, or medinal (sodium salt of barbitone),
- (3) propional (di-propyl-barbituric acid),
- (4) neonal, or soneryl (N. butyl-ethyl-barbituric acid),
- (5) dial (di-allyl-barbituric acid),
- (6) phenobarbitone, or luminal (di-phenyl-barbituric acid),
- (7) sodium luminal,
- (8) phanodorn (cyclo-hexenyl-ethyl-barbituric acid),
- (9) evipan (N. methyl-cyclo-hexenyl-methyl-barbituric acid),
- (10) sodium evipan,
- (11) pento-barbitone (ethyl-methyl-butyl-barbituric acid) and
- (12) its sodium salt, nembutal,
- (13) ipral (calcium ethyl iso-propyl-barbituric acid),
- (14) allonal (a combination of allyl-iso-propyl-barbituric acid with amidopyrin),
- (15) veramon (a combination of veronal with amidopyrin),
- (16) somnifaine (a combination of dial and amidopyrin),
- (17) cibalgin (a combination of dial and amidopyrin),
- (these last four all produce a reddish-brown colour in urine on account of the presence of amidopyrin),
- (18) gardenal (phenyl-ethyl-barbituric acid),
- (19) sodium hebaral (sodium salt of hexyl-barbituric acid),
- (20) beatol (a proprietary preparation said to be a mixture of veronal with extracts of valerian and jusquiame),
- (21) quadronox (a proprietary preparation said to contain 80 per cent veronal with phenacetin, phenazone, etc.; urine may be coloured reddish-brown from the phenazone present),
- (23) amytal (iso-amyl-ethyl-barbituric acid),
- (24) pernocton (2 butyl-brom-ethyl-barbituric acid),
- (the sodium salts of both these are used by the intravenous route to produce anaesthesia),
- (25) nastal (iso-propyl-brom-allyl-barbituric acid), and
- (26) sandoptal (iso-butyl-allyl-barbituric acid).

The addition of alkyl or aryl radicles of higher molecular weight than ethyl adds to the toxicity of the substance, thus luminal, dial, propional, gardenal, soneryl and nembutal are all more toxic than veronal. Launoy and Contiere, taking veronal as unity, have found that the relative toxicity for dial is 3.1, for soneryl 4.7, and for both amytal and nembutal 10.1. It is therefore safer to use for hypnotic purposes barbitone or its sodium salt than the more complex derivatives. Although these drugs as a rule are not very toxic and the average minimum fatal dose for barbitone (veronal) is 3 to 4 grammes (45 to 60 grains) deaths have occurred from much smaller doses, e.g., 1 gramme or 15 grains given in one dose. On account of their easy availability they have been used for suicidal purposes.

The combination of a barbituric acid compound with an analgesic drug, such as amidopyrin, phenacetin, etc., occurs in veramon, allonal, cibalgin, somnifaine and quadronox. Such combinations are likely to have more toxic effects on the organism and frequent repetition of therapeutic doses may produce serious effects.

Wagner (1933) has divided the barbituric acid compounds into two groups, (1) the shorter-acting drugs, which are eliminated rapidly and whose cumulative effects are not marked; to this category belong pento-barbital sodium, amytal and secondary butyl beta

brom-allyl-barbituric acid sodium salt, and (2) the longer-acting drugs, which are eliminated slowly, have marked cumulative effects and lead to delirious reaction or other toxic symptoms: to this category belong phenobarbital, neonal, ipral, a barbituric derivative with amidopyrin, dial and barbital. It may be generally said that combination with sodium makes the compounds more rapid in their action. The degree of toxicity of these compounds according to this author starting from the highest is as follows: secondary butyl beta brom-allyl-barbituric acid sodium salt, barbital, phenobarbital, amytal, neonal, a barbituric derivative with amidopyrin, dial and pentobarbital sodium.

Action and use.—The physiological effects of these compounds comprise not only a specific hypnotic action on the brain, but also on the lungs, heart and kidneys. The heart rate is quickened, vasodilatation is produced and the blood pressure falls partly owing to vasodilatation and partly to the toxic action of the drugs on the myocardium; the pulse may become intermittent. In severe cases death may occur from heart failure. In certain patients, such as those suffering from hyperthyroidism, exophthalmic goitre or severe toxæmia, sepsis, etc., the toxic effects of barbituric acid compounds are greatly enhanced so that even an ordinary therapeutic dose may produce dangerous symptoms or even fatal results.

They produce a slight fall in the body temperature; the basic metabolic rate is little affected; they have no appreciable effect on blood sugar; the calcium content of the blood is definitely decreased. All members of this series depress the respiratory system and produce physical signs of broncho-pneumonia. The urinary output is appreciably diminished but the flow returns to normal within about 24 hours; drugs like nembutal are said to produce suppression of urine. Some workers have found a slight but transient damage to the liver, others consider very little action on the hepatic function. The tone of the gastro-intestinal muscle is decreased. So far as the nervous system is concerned the threshold for painful stimuli is decidedly increased and during deep narcosis no response to painful stimuli can be obtained. The pain has been controlled in patients with tabetic crises. Large doses, or in susceptible individuals even small doses, may cause a drowsy condition accompanied by fever and rapid development of coma. The psychological effects of these compounds have been worked out; after administration of these drugs there is a striking change in the emotional attitude of the subjects and a definite feeling of euphoria is said to be obtained.

The barbituric acid derivatives are perhaps the most commonly used hypnotics at the present day. When taken by the mouth they are quickly absorbed and within an hour or so after a clinical dose sleep usually ensues. After a single therapeutic dose a period of sleep lasting from six to twelve hours usually occurs,

without unpleasant after-effects. There is more certainty of action than with most of the other hypnotics, with the exception of opiates, and this is the reason for the popularity of this group of hypnotics. Many of the drugs mentioned have been used for basal anaesthesia, those which are most commonly used at the present time being nembutal, pernocton, amytal and evipan. On account of their effective sedative properties, they are used in the treatment of hysteria, neurasthenia, chorea and epilepsy.

Toxic effects and habit formation.—In a paper in the *Lancet*, Sir James Purves-Stewart and Sir William Willcox (1934) have described a series of cases of poisoning by barbitone and allied drugs. Besides the toxic effects produced by massive doses of these compounds they also produce dangerous cumulative effects when repeated in therapeutic doses and there is a tendency to habit formation. These facts have not been sufficiently appreciated by the medical profession in India. During recent years the use of barbituric acid derivatives has considerably increased in India and a number of compounds, particularly luminal, veronal, medinal, veramon and adaline, are being largely used by medical practitioners. On account of their marked hypnotic and analgesic properties, less disagreeable taste and irritant effects, they are preferred to the chloral and sulphonal group of drugs. The lay public have also begun to use them, without medical advice, for the purposes of producing sleep or relieving pain, with the result that in quite a number of cases habit formation have occurred.

The question of habit formation with these drugs has been discussed by Gillespie (1934) and he has brought forward certain *a priori* considerations against the likelihood of the frequent occurrence of this.

While engaged in the study of drug habits in India we have been making enquiries regarding the use of these drugs by the public and have found that habit formation does sometimes follow the use of members of this group of drugs. Our enquiries show that addiction is still uncommon, but, as there are no restrictions to the sale of these drugs, there is likelihood of the extension of this practice. Instances of abuse of these drugs are at present confined to large towns only. We have been informed that certain members of this group are being employed by young licentious individuals and by prostitutes for their sexual effects, and it has been alleged that they have been employed for stupefying young girls for immoral purposes. We have, however, not been able to trace any case of this nature. The use of barbiturates is at present confined to the educated classes, probably because they have opportunities of reading notices in the medical and the lay press extolling the hypnotic and

analgesic properties and alleged freedom from toxic and harmful effects of these drugs, and thus they start self-medication.

The following cases which have come to our notice are typical examples of the abuse of these drugs :—

(1) S. L., a Hindu male, aged 22, an intelligent and healthy-looking young man, was working as a compounder with a medical practitioner in Gujranwala. In April 1928 he suffered from acute bronchitis and could not sleep for four nights. He prescribed himself two tablets ($7\frac{1}{2}$ grains each) of sodium barbitone which procured him good sleep. This dose was repeated every alternate night before going to bed, for a period of a fortnight, after which it was discontinued. Although his cough was alleviated, the patient could not sleep and again resorted to the drug. On being warned he stopped the drug for a few months but was so much troubled with insomnia and irritability of temper that he secretly continued the drug off and on for a period of 3 years, sometimes taking as much as 4 tablets (30 grains) in 24 hours. During this time the patient suffered from progressive anaemia and loss of weight, but carried on his work. In January 1932 he showed signs of exhaustion, inability to concentrate and was compelled to abandon his work. He suffered from palpitation, marked asthenia, unsteady gait, tremors of the hands and feet, and a sinking feeling in the chest. He looked very pale and anæmic; his total red cell count was 3,500,000 and hæmoglobin 75 per cent. The upper eye-lids were puffy and slightly swollen; the urine was scanty, high-coloured and showed traces of albumin; he had tachycardia, and hæmic murmurs were present. There was severe headache and slow cerebration. This condition lasted 3 months, the patient still continuing to take two tablets of this drug daily.

The patient now came under treatment, the drug was withdrawn without any difficulty and general measures, such as hot foot-baths, sponging, massage, etc., were adopted to combat insomnia. An alkaline mixture containing 10 grains each of bromides of ammonium and potassium with 10 minims of tincture of digitalis was prescribed. After a week's treatment little or no improvement was observed in the mental condition, although the general condition was better. Insomnia however was so troublesome that he secretly arranged to buy a phial of sodium barbitone. On the 20th January he took two tablets at 6-30 p.m. without getting sleep; at 8-30 p.m. two more were taken. Half an hour after the second dose he became dyspnoic and sleepy, and went to bed at 9-15 p.m. Coma supervened and the patient became cyanosed; the temperature rose to 103°F . and the pulse rate to 130 per minute; the breathing became stertorous and laboured; there were physical signs of broncho-pneumonia in both lungs. The stomach was immediately washed out with a weak solution of potassium permanganate, digitalin and strychnine were administered hypodermically, and oxygen inhalations were started. About 3 pints of normal saline with glucose were given subcutaneously, but the patient expired in a comatose condition on the 23rd of January.

Case 2.—X., an educated Hindu male, aged 28 years, of highly neurotic temperament, had been a morphine addict since 1928. The drug was administered to him after an attack of biliary colic and the habit was thus started. His father consulted the writers and, under their advice in December 1933, morphine was completely withdrawn with the help of insulin injections without any untoward effects. The patient, however, suffered from insomnia and to combat this condition a pill containing $7\frac{1}{2}$ grains of sodium barbitone was administered for 4 consecutive nights by the doctor in charge. This procured sleep but when the drug was stopped insomnia returned. This was

only partly overcome by other measures for a few weeks. The patient then secretly bought a bottle of sodium barbitone and started taking it in doses of $7\frac{1}{2}$ grains daily. One pill was enough to produce sound sleep in the beginning, but after some time he had to resort to 2 pills to obtain the desired effect. This continued for about 6 weeks during which period the patient became extremely pale and listless, suffered from tremors of the hands and feet, dimness of vision, tinnitus and thickness of speech. The drug was completely withdrawn and the patient was carefully watched. He was given a nourishing diet and a tonic mixture containing iron, arsenic and strychnine. These measures succeeded to a certain extent in the beginning, but later on it was thought necessary to administer opium in $\frac{1}{4}$ grain doses daily along with general measures. Within 3 weeks' time the patient gained in weight, started taking an interest in life, and became mentally normal. Later, opium also was successfully withdrawn.

Case 3.—F., an Anglo-Indian female, aged 25, unmarried, had much worry on account of family affairs, and suffered from sleeplessness. Under the advice of a doctor she started to take sodium barbitone occasionally. One to two pills were enough to procure her sound sleep and this was continued for some months. The patient then began to suffer from dullness and heaviness in the head, irritability of temper, breathlessness on exertion and listlessness. The drug was discontinued at once and the dangers of this form of self-medication were explained to the patient. There were no untoward symptoms and the patient regained her normal health in a month and so far as is known has not gone back to the drug.

Discussion.—An analysis of the cases of poisoning and of abuse of these drugs in this country for the last five years occurring in the reports of chemical examiners of different provinces shows that most of the cases were addicted to the use of some other drug at the same time. In some cases, barbitone, or one of its derivatives, was used by itself, but, in others the drug was taken by those using alcohol and cocaine to overcome insomnia produced by their excessive use. Persons with unstable nervous systems under worry and strain may resort to these drugs. We have seen cases where death of some near relative, losses in business, or the maladjustment of domestic affairs have induced their use, either under the advice of the family physician or independently, in order to allay the uneasiness of mind from which they suffered.

In a number of instances we have observed that although these drugs were continuously used for weeks together they did not lead to the intense type of addiction usually produced by opiates. Although the abstinence symptoms on withholding the drugs are absent and the drugs can be suddenly stopped without any difficulty, there is a distinct desire for repeating the dose for control of symptoms for which the drug is taken. We have on record cases of certain individuals who in the first instance took these drugs in order to overcome the feelings of fatigue, worry and insomnia, as they could not afford the use of expensive euphorics like alcohol, or were afraid of using opium on account of the risk of habit formation. These persons exhibited a strong desire to repeat the

dose towards the evening. The feeling disappeared rapidly after taking the dose and before the drug was actually absorbed into the system, indicating that there was a strong psychic factor.

It is believed by some practitioners in this country that drugs of this series cure drug addiction. Luminal, medinal and pronoclon are not uncommonly prescribed to combat insomnia resulting from withdrawal of drugs like opium, morphine, cocaine and alcohol. In a number of cases these addictions were overcome and beneficial results were produced, but in a few instances the individuals became habituated to the drug in addition to the original drugs of addiction.

The usual sequence of events is to start with a therapeutic dose of 5 to 10 grains for a few weeks in the form of a pill at bedtime, but soon the ordinary dose becomes ineffective and it becomes necessary to increase the dose to achieve the desired effect. As little or no tolerance is developed, toxic symptoms set in quite early after a comparatively small increase in dosage. The average toxic dose in Indians ranges between 60 to 80 grains, though untoward effects have been produced with therapeutic doses, especially in persons with damaged hearts, lungs and kidneys. The excretion of these drugs appears to be slow and may extend over a period of 5 to 7 days, and probably this accounts for certain instances of fatal poisoning after repeated therapeutic doses.

We have not come across any case where the habit had lasted for more than five years. Most of the patients were compelled to give up the habit or, if they persisted, succumbed to some intercurrent disease. Persons between the ages of 30 to 50 are more prone to their use, as at this age they are more active and subject to greater mental strains.

According to Gillespie (1934), in the majority of instances barbiturates produce nothing resembling the euphoria of alcohol or morphine. On the contrary, patients sometimes complain of discomfort following their use. Lindemann (1932) studied the psychological effects induced by small doses of sodium amytal. In healthy individuals he found there was a striking change in the emotional attitude of the subjects. There was a feeling of well-being and serenity, a feeling of warmth and friendship towards the world in general, and gratitude and appreciation for the kindness and goodness of friends and associates. There was thus a distinct production of euphoria. In psychotic patients also similar changes in the emotional reaction were observed. Our own experience in this respect is limited, but in the cases that have come under our observation among Indians the symptoms of euphoria, such as those described, were not present. The patients wanted to repeat the

dose for relief of some symptom rather than for the euphoric effects of the drug, as is the case with opium, hemp drugs and alcohol.

In this connection it may be pointed out that there is no control whatever in this country over the sale of these drugs, anyone can buy them in any quantity and their use by the lay public is increasing. In Great Britain all the barbituric acid derivatives are placed in part II of the Poisons Schedule, 1918, i.e., they cannot be dispensed without the prescription of a qualified medical man. In India, however, they are not classed as poisons and are therefore not included in any of the schedules of the Poisons Act of 1919 (amended in 1931). The need for bringing the sale of this group of drugs, as well as of the hypnotics of chloral and sulphonal series, under control in this country is very urgent.

Summary and conclusions

(1) The use of barbituric acid derivatives has greatly increased in India during the last few years. These compounds have powerful hypnotic and pain-relieving properties being only second to opiates in this respect.

(2) The fact that this group may produce toxic effects even in therapeutic doses and are cumulative in their action has not been sufficiently appreciated by the medical profession.

(3) Their repeated use is harmful and dangerous, definite pathological changes being produced in vital organs. No tolerance is developed and any increase of dose may give rise to dangerous symptoms and even fatal results. The margin between toxic and therapeutic doses is very narrow and certain individuals are particularly susceptible to the action of these drugs. Caution is therefore recommended in their use.

(4) Habit formation has occurred with these drugs in Indian subjects, but the desire for the repetition of the dose is more for relief of symptoms than anything else. They do not appear to produce euphoria like opiates, hemp drugs and alcohol. Abstinence symptoms are not produced and habit can be easily broken.

(5) The need for bringing this group of drugs under control, similar to that exercised in Great Britain, is emphasized.

BERNHARDT'S SYNDROME

By E. MUIR, M.D., F.R.C.S. (Edin.)

and

S. N. CHATTERJI, M.B. (Cal.), D.T.M. (Bengal)

School of Tropical Medicine, Calcutta

This condition, originally described by Martin Bernhardt of Berlin (Otto Sittig, 1933), is of not infrequent occurrence in Calcutta, no fewer than twelve cases having been diagnosed among patients appearing at the leprosy clinic of the School of Tropical Medicine during the year 1934. The lateral cutaneous nerve of the thigh after emerging from the pelvis under Poupart's ligament passes either anterior to, posterior to, or through the upper end of the sartorius muscle (see figure). When it passes through the muscle and, especially if there be some fibrositis of the muscle, the nerve is liable to be constricted. In consequence of this, sensory symptoms appear in the skin area of distribution, *viz*, the lateral surface of the thigh. There is a sense of heaviness felt by the patient, and an area of skin large or small in extent is found to be anæsthetic to light touch in most cases and sometimes also anæsthetic to pain.

In India, by far the commonest cause of these symptoms is leprosy; for this reason such cases are frequently suspected of suffering from this disease and find their way to the leprosy clinic. Definite exclusion of leprosy will often afford great mental relief to the patient.

In leprosy lesions of the neural type there are, in addition to anæsthesia, almost invariably

other local signs, *viz*, keratosis, hyperpigmentation, depilation, anhydrosis, and sometimes palpable thickening of the adjacent sensory nerve branches; there may or may not be a visibly raised and erythematous margin to the affected skin area. All these are absent in Bernhardt's syndrome. Moreover in the latter condition the anæsthetic area, when mapped out carefully, is regularly round or oval in shape and confined to the antero-lateral side of the thigh; whereas the margin of the leprosy lesion tends to be irregular in shape and to extend over the front of the thigh or down to the knee.

The following are short notes on the twelve cases of Bernhardt's disease mentioned above:

1. Sk. S., age 30 years. Tingling sensation in left thigh, duration 20 days' anæsthesia to light touch and to pain.
2. B. B., age 45 years. Tingling and numbness on the lower part of the antero-lateral aspect of the thigh; duration one month; slight anæsthesia to light touch and to pain. Pyorrhœa and anæmia with a history of malaria.
3. B. G., age 30 years. Anæsthesia to light touch but not to pain in the antero-lateral aspect of the left thigh.
4. N. R., age 25 years. Anæsthesia to light touch in antero-lateral aspect of right thigh.
5. Bh., age 35 years. Complaints of anæsthetic area on left thigh for three months; on shaving the part, areas anæsthetic to light touch and to pain were found. There were similar but slighter subjective symptoms on the right side. There was a history of syphilis and gonorrhœa 15 years previously.
6. H. K., age 41 years. Anæsthesia to light touch and to pain. Feeling of numbness for 10 years. In this case the diagnosis of Bernhardt's syndrome was made in spite of the history that the patient's father had suffered from leprosy.
7. D. M., age 32 years. Complaints of anæsthesia and a burning sensation over the antero-lateral aspect of the right thigh. Objective examination was however negative for anæsthesia.
8. N. B., age 40 years. Burning and tingling in right thigh for 1 year. Anæsthesia to light touch and to pain.
9. R. U., age 45 years. Complaints of loss of feeling in left thigh for 1½ years. Anæsthesia to light touch and to pain were found on examination.
10. J. H., age 26 years. Tingling sensation in the left thigh for 1 month. On examination anæsthesia could not be elicited.
11. M. H., age 30 years. Anæsthesia of right thigh for 10 days. On examination we found anæsthesia to light touch and to pain.
12. B. P., age 38 years. Complaints of anæsthesia on the outer side of right thigh for 6 months. Anæsthesia to pain was found on examination. This patient was himself a doctor and had treated many leprosy cases.

In none of these cases was there any palpable thickening of local nerve branches, nor was there any difference in the appearance of the affected area when compared with the surrounding skin.

Anæsthesia to light touch was elicited by blind-folding the patient, touching affected and unaffected areas, and asking the patient to indicate with his finger the points touched. Pain was tested by pricking simultaneously

THE RETICULO-ENDOTHELIAL SYSTEM IN MALARIAL HÆMOGLOBINURIA OF MONKEYS

By K. V. KRISHNAN, M.B., B.S., M.R.C.P., D.B., D.Sc.

(From the Department of Malariology, All-India Institute of Hygiene, Calcutta)

Introduction

WITHIN the last decade or two, several workers in different parts of the world have investigated extensively the reticulo-endothelial system and its functions. The results of their studies indicate that the system performs many important functions in health and in disease (Aschoff, 1924; Hadfield and Garrod, 1932). In 1929 therefore the writer commenced his studies on the rôle of the reticulo-endothelial system in some of the important protozoal diseases, such as malaria and kala-azar. The results relating to malaria obtained by him suggested that upon the powers of mobilization, proliferation and functional activation of the

(Continued from previous page)

with two pins the corresponding points on the two thighs, the patient being asked to indicate on which side he felt the prick most. It will be noticed that the age period of all the cases was between 25 and 45 years of age.

In contrast to the above may be mentioned two other cases which were diagnosed as suffering from leprosy:

C. S., age 36 years. Complaints of loss of sensation in the lower part of thigh extending to knee, duration 3 years. Over the affected area there was slight hypopigmentation. There was loss of pain sensation. A branch of the nerve supplying the part was palpably thickened. This was excised and sectioned; it showed dense granulomatous cell infiltration typical of leprosy.

K. S., age 28 years. Anæsthesia to light touch, pain and slight erythema of an area on left thigh. The left lateral femoral cutaneous nerve was palpably thickened.

Treatment

Syphilis, gonorrhœa and various septic conditions appear to be among the most common causes which provoke Bernhardt's disease. These should be carefully searched for and treated if present. Removal of these conditions may be sufficient to relieve the patient.

In others, the intravenous injection of stock vaccine in increasing amounts, the dose being increased only when the previous one fails to produce any marked febrile reaction.

Another form of treatment which has been found useful is diathermy, the one electrode being placed over the point of emergence of the lateral cutaneous nerve from the pelvis into the thigh, and the other over the anæsthetic area.

phagocytic mononuclear cells composing the reticulo-endothelial system depends resistance in malaria, and that experimental damage to the system, as for example by splenectomy, results in a partial or complete failure of both natural and acquired immunity, and in a lowering of the therapeutic value of specific drugs like quinine (Krishnan *et al.*, 1932 to 1934). In the course of these investigations, the impression was gained that the incidence of hæmoglobinuria in monkeys infected with *Plasmodium knowlesi* was higher in those animals in which experimental damage or dysfunction of the system was caused. This observation led the writer to investigate the matter further and to undertake a systematic study of the rôle of the reticulo-endothelial system in malarial hæmoglobinuria in monkeys and to determine the factors that led to an enhancement or lowering of the functional efficiency of the reticulo-endothelial system. Accounts of the experiments performed, the observations made and the conclusions reached are presented in this and other papers now in preparation.

Review on malarial hæmoglobinuria in the monkey

In 1932 Napier and Campbell discovered a monkey plasmodium which has since been named *Plasmodium knowlesi* Sinton and Mulligan. This plasmodium, while causing a low-grade infection in *Silenus irus* and *S. radiatus*, produces an intense fatal infection in *S. rhesus*. In the latter species a certain number of animals dying of severe infection develop hæmoglobinuria. At first it was thought possible that *P. knowlesi* might be a highly-virulent hæmolytic strain, which on account of its virulence caused hæmoglobinuria in monkeys and that it would cause possibly blackwater fever in man; but, as it failed to produce hæmoglobinuria in the *irus* or *radiatus* monkeys, or in the few men who were experimentally infected with it (Knöwles and Das Gupta, 1932), this view was considered untenable. It was next thought that hæmoglobinuria occurred only in *rhesus* monkeys, because of the greater susceptibility of this species to plasmodium infections. In these animals hæmoglobinuria was invariably associated with a massive infection (of over half a million parasites per c.mm. of blood), and it was easy to conceive how hæmoglobinuria would readily result when during sporulation such enormous numbers of infected red cells were disrupted and a large amount of hæmoglobin was liberated into the circulating blood. This hypothesis however had to be modified in the light of the finding that all susceptible *rhesus* monkeys showing a heavy parasitization did not develop hæmoglobinuria. Only in about 30 per cent of all infected *rhesus* monkeys and in 60 per cent of the heavily-infected ones was hæmoglobinuria noticeable. An explanation

had to be found for its absence in the other 40 per cent of susceptible animals. The question was why did not these *rhesus* monkeys develop hæmoglobinuria despite a heavy infection? Is it because of their increased capacity to deal with this hæmoglobin? If so, what is the basis of this increased capacity? Is there any noticeable difference (eytological, serological or biochemical) between these two groups of *rhesus* monkeys (one showing heavy infection with hæmoglobinuria and the other showing heavy infection without hæmoglobinuria)? Why did not the *irus* and *radiatus* monkeys develop hæmoglobinuria? Is it merely because of the low-grade nature of their infection or is there any other factor concerned as well? Could the infection be intensified in these species and would hæmoglobinuria result when a heavier infection was induced in them? If so, what is the factor concerned in increasing the intensity of infection and incidence of hæmoglobinuria, and what relationship has that factor to the reticulo-endothelial system?

From the literature on malarial hæmoglobinuria in monkeys and on blackwater fever in man, and from the writer's previous studies on malaria, he came to the conclusion that through an investigation of the eytological, physiochemical and biochemical alteration of the blood with special reference to phagocytosis and proliferation of monocytes, regeneration and destruction of red cells, and through splenectomy experiments it would be possible to answer some of the above questions relating to malarial hæmoglobinuria in monkeys in a satisfactory manner.

PART I

Reticulo-endothelial cell changes in the blood of monkeys developing malarial hæmoglobinuria, and their significance

It is generally believed that from a careful study of the alterations in the peripheral blood of normal and infected animals it is possible to obtain valuable information regarding the defence processes at work during the invasion of a host by a micro-parasite. This is even more true in an infection in which the site of the struggle between host and parasite is principally in the peripheral blood; that is so because, if the infection is to be overcome completely by the host, it will be only through a rapid and successful mobilization of its defence forces at the site of the struggle, *i.e.*, in the blood, in the present instance. If this view is correct, then the variations in the blood picture seen during the course of an infection can be assumed to reflect fairly accurately the defence processes at work and through a correct interpretation of these changes an idea of the ætiological and immunological factors concerned may be obtained.

It has already been stated that the hæmoglobinuria of monkeys, which we are studying, is associated with a plasmodial infection which causes a heavy parasitization of the red cells of the blood, and that the hæmolysis of a large number of infected red cells and the consequent liberation of an enormous quantity of hæmoglobin into the circulating blood results in the hæmoglobinuric state in some of the animals, while in others the condition fails to develop. It may therefore be assumed that the factors responsible for the production of hæmoglobinuria in the first group and its prevention in the second would be manifest in the peripheral blood and that a comparative study of the two groups would be invaluable. Furthermore, as it is being increasingly recognized that the reticulo-endothelial cells (commonly known as large mononuclear cells, histiocytes and monocytes) are primarily concerned in the disposal of damaged and dead red cells, as well as of free hæmoglobin from the circulating blood, it follows that, through a study of the changes in reticulo-endothelial cells with regard to their mobilization, proliferation and functional activity during the pre- and post-hæmoglobinuric states, valuable information may be gathered regarding their rôle in the production or prevention of hæmoglobinuria. This then is the basis for the experiments recorded in this article.

Material and technique

In this experiment the monkeys used were all *S. rhesus*. The plasmodium was a pure-line strain of *P. knowlesi*. The technique used for identifying the reticulo-endothelial cells was the supravital staining technique (Napier, Krishnan and Lal, 1932). These cells were classified as monocytes and histiocytes according to their capacity to phagocytose neutral red. Total and differential counts of leucocytes were also done. Serial observations were made from the day the animals began to show parasites in their peripheral blood to the day of their death or recovery with or without hæmoglobinuria, treated or untreated. In this article the results of observation on 25 monkeys are presented. Many more were studied but those that showed mild infection were excluded. The monkeys included here are divided into two groups, group I consisting of 14 monkeys developing heavy infection and hæmoglobinuria, and group II consisting of 11 monkeys not developing hæmoglobinuria despite a heavy infection comparable to that of those in group I. By the term heavy infection is meant a parasite count of 0.2 to 0.5 million per c.mm. corresponding roughly to over 50 parasites per field. As monkeys of both groups invariably tended to die if left untreated, quinine was administered by injection to approximately half the number in each group. The untreated monkeys are included in sub-group A, and the treated in

sub-group B. The alterations in the reticulo-endothelial cells after the administration of quinine was also noted.

Results.—These are presented in tables I and II.

TABLE I

Showing the percentage of the reticulo-endothelial cells in the blood of monkeys of group I and group II. The counts represent those obtained 12 to 24 hours prior to the onset of hæmoglobinuria in monkeys of group I and are comparable with the counts in monkeys in group II which developed no hæmoglobinuria despite a heavy infection

	Total leucocytes per c.mm. of blood	Percentage monocytes	Percentage histiocytes	Percentage of total reticulo-endothelial cells
Group I	13,000	1.5	2	3.5
	10,000	1.5	2.5	4
	14,000	1	2	3
	10,000	0	6	6
	20,000	1.5	4.5	6
	15,000	2	4	6

It will be seen from table I that there is a distinct difference in the counts of reticulo-endothelial cells in the two groups of monkeys studied.

Before interpreting the results it would be profitable to review the previous work on the subject. In the past, several workers have studied the leucocyte changes in blackwater fever in man. The counts obtained by them were very variable and depended among other things on one factor, namely, the stage of the disease at which the examination was made, whether shortly after or long after the onset of hæmoglobinuria. Stephens and Christophers (1900) and Christophers and Bentley (1908) drew attention to a definite increase in the large mononuclear cells during and after hæmoglobinuria. Others have confirmed this (Ross,

1932).^{*} From these it seems that during and immediately after an attack of blackwater fever there is generally a tendency for the large mononuclear cells to increase. This may be interpreted as the host's reaction to red cell destruction, and liberation of free hæmoglobin. As it was not possible in these studies to determine the blood changes prior to the onset of hæmoglobinuria, and to correlate the subsequent leucocytic changes with either recovery or a fatal termination, no conclusion regarding the mechanism of production of hæmoglobinuria and the part played by the reticulo-endothelial cells in it was possible. Furthermore, it is now recognized that for a correct identification of the reticulo-endothelial cells and for a proper estimation of the functional capacity, the supravitral technique is the method of choice. By the use of this technique as a routine for the study of the reticulo-endothelial cells in the blood of infected monkeys in all our experiments, it has been possible to obtain more valuable information than previously. From the results in table I, it will be seen that in the pre-hæmoglobinuric state, in monkeys of group I, there is a reduction in the number of reticulo-endothelial cells compared to group II monkeys. This difference is significant so far as group I is concerned because it is present in spite of heavy infection which is a natural stimulus for the mobilization of the reticulo-endothelial cells. In group II, where the mobilization is marked, hæmoglobinuria did not result although the monkeys showed as heavy an infection as the monkeys in group I. In the course of this experiment it has been possible on several occasions to predict correctly the onset of hæmoglobinuria, or its absence, from a knowledge of the blood picture. Furthermore, it was noticed that the reticulo-endothelial cells in group I monkeys, just before hæmoglobinuria occurred, were functionally less active. The amount of neutral red ingested by them was very much less than that ingested by those in group II monkeys. From this we are led to believe that in the pre-hæmoglobinuric state there is a depression of function of these cells. Another observation made having a bearing on the subject is that in group I monkeys that developed hæmoglobinuria the maximum intensity of infection was reached in a very much shorter time than in group II monkeys. The average number of days elapsing from the day of first appearance of parasites in the blood to the day of heavy infection was 4 days in group I and 7.5 days in group II. The rapid development of infection and the suddenness of the severe hæmolysis may influence somewhat the onset of hæmoglobinuria. From such evidence we are led

^{*}In paroxysmal hæmoglobinuria according to Stephens a preliminary leucopenia is followed by a leucocytosis. Similar results were also obtained by others.

to believe that a damaged reticulo-endothelial system is a prerequisite to malarial hæmoglobinuria. When hæmolysis occurs and a large amount of hæmoglobin is liberated, under such a condition, the reticulo-endothelial cells fail to remove all the hæmoglobin, its concentration in the blood rises, the threshold limit of the kidney is passed and hæmoglobinuria results. This is probably what is happening in group I monkeys. If on the other hand the reticulo-endothelial cells are active and present in required numbers, the same amount of hæmoglobin liberated as in the first instance is rapidly engulfed and disposed of, is not allowed to pass above the threshold limit of the kidney, and no hæmoglobin is passed in the urine. This is probably what is taking place in group II monkeys.

Table II shows the fates of the infected monkeys of groups I and II. They are divided into sub-groups A and B according as they were untreated or treated.

TABLE II

	SUB-GROUP A UNTREATED			SUB-GROUP B TREATED		
	Total	Survived	Died	Total	Survived	Died
Group I showing hæmoglobinuria.	7	0	7	7	2	5
Group II showing no hæmoglobinuria.	6	2	4	5	4	1

It will be seen that the mortality was generally higher in group I than in group II and that treatment produced better results in group II than in group I. The cause of these differences was investigated by a study of the reticulo-endothelial cell response after hæmoglobinuria and treatment. The reticulo-endothelial cell counts were done daily after the onset of hæmoglobinuria and after treatment was started till recovery or death of the animal took place. The nature of the counts obtained in those that improved and lived, and in those that did not, is discussed below.

In group I-A, all the seven monkeys died of hæmoglobinuria. As four of them died soon after the onset, no more counts could be done on any of these. Of the other three, two survived for a little over 24 hours after the onset of hæmoglobinuria and one for 4 days. The large mononuclear count of one of the two former was the same as previous to the onset of hæmoglobinuria, i.e., very low. The count of the second was higher and showed a rise from

4 to 14 per cent after the attack. It, however, died despite this rise. In the monkey that lived for 4 days the count rose from 6 to 30 per cent within 24 hours of the onset of hæmoglobinuria, and later fell to 7 per cent before death, on the fourth day. Hæmoglobinuria disappeared temporarily for 48 hours after this rise and the infection also became less intense. On the day of its death an intensification and a recurrence of hæmoglobinuria occurred.

In group II-A, two out of six animals recovered from the infection and in each case the recovery was preceded by a marked increase in the number of reticulo-endothelial cells (from 11 and 17 per cent the counts rose to 28 and 35 per cent, respectively). The other four that died showed a reticulo-endothelial count varying from 11 to 30 per cent. One important noticeable difference between those that recovered and those that died was that functional activity of the reticulo-endothelial cells was marked in the former but less so in the latter. Furthermore, there was evidence of red cell regeneration in the former (reticulocyte count being 10 to 35 per cent) but not in the latter (the reticulocyte count was 1 to 2 per cent only). Death in these cases was attributable to the absence of a sufficient number of red cells to maintain life. Young and dividing monocytes, which are generally to be found in the blood of animals that recover, are invariably absent in the bloods of those that die. This suggests that proliferation of reticulo-endothelial cells is less, and replacement of old by new cells is not adequate.

In group I-B, despite treatment only two out of seven monkeys recovered. Here again recovery was associated with a high reticulo-endothelial cell count varying from 20 to 25 per cent. In the five that died, death occurred within 24 to 48 hours of the commencement of treatment and no appreciable change was noticed in the counts done before and after treatment of the attack.

In group II-B, treatment was able to produce better results than in all the other groups, only one out of five dying. Here again the improvement was associated with a marked rise in reticulo-endothelial cells. The counts which varied from 10 to 15 per cent before treatment rose to 25 to 38 per cent after treatment and during recovery. The reticulocyte counts were also very high and sometimes rose as high as 30 to 35 per cent. In the animal that died the reticulo-endothelial cell count remained constant after treatment without any appreciable change till death. The reticulocyte count was found to be very low (less than 2.1 per cent).

Summary and conclusions

From the above results it seems that both the number of reticulo-endothelial cells present as

well as the functional state of these cells are important factors in determining hæmoglobinuria. Death or recovery from the condition appears also to be dependent upon the degree of red cell regeneration. This will have to be taken into account in the consideration of the ætiology or prevention of malarial hæmoglobinuria. The study of the factors that increase and retard the phagocytic powers of the reticulo-endothelial cells and influence their proliferation appear to be of importance. They will have to be properly understood before definite conclusions are reached regarding malarial hæmoglobinuria. At the present stage it seems justifiable to draw the following conclusions :

1. That the reticulo-endothelial system probably plays an important part in the ætiology and prevention of malarial hæmoglobinuria.

2. That, when the system is depressed, as is evidenced by a low reticulo-endothelial cell count and inability to take up large quantities of vital dyes, sudden severe hæmolysis results in hæmoglobinuria.

3. That, when the system is active and functioning properly, as is evidenced by a high reticulo-endothelial cell count and ability to engulf large amounts of vital dyes, sudden severe hæmolysis does not result in hæmoglobinuria.

THE RETICULO-ENDOTHELIAL SYSTEM IN MALARIAL HÆMOGLOBINURIA OF MONKEYS

PART II

THE RELATION OF SPLEEN TO HÆMOGLOBINURIA

By K. V. KRISHNAN, M.B., B.S., M.R.C.P., D.B., D.Sc.
and

B. M. GHOSH, M.B., D.P.H.

(From the Department of Malariology, All-India Institute of Hygiene, Calcutta)

It is generally accepted that of the many ways of studying the problems relating to the reticulo-endothelial system splenectomy is one of the most valuable and popular methods. The spleen being one of the organs rich in reticulo-endothelial cells, the removal of the organ is assumed to result both in the lowering of the total number of reticulo-endothelial cells and in the diminution of the functional capacity of the remaining cells. On the basis of this assumption extirpation of the organ has been widely practised in connection with studies relating to the function of this system. The results obtained, however, have not come up to expectation in all cases. Without going into the reasons for the variable nature of the results obtained in different diseases (Krishnan, 1932) it is enough to state that, so far as the rôle of the system in monkey malaria is concerned, splenectomy experiments have yielded valuable and conclusive results. The senior writer showed (Krishnan, Smith and Lal, 1933) that removal of the spleen in all species of monkeys made the animals more susceptible to *Plasmodium knowlesi* and that it invariably resulted in an intensification of the infection followed by hæmoglobinuria and death in the majority of instances. This work has since been corroborated by (Sinton and Mulligan, 1933, and Knowles and Das Gupta, 1934). During these splenectomy experiments the senior writer noticed, for the first time, that the *irus* and *radiatus* monkeys which had never previously been known to suffer from malarial hæmoglobinuria developed the condition quite frequently after the removal of the spleen. This in fact led to a thorough study of the part played by the spleen in malarial hæmoglobinuria. Furthermore, in a previous paper the senior writer (Krishnan, 1935) from a study of the reticulo-endothelial cell alterations in malarial hæmoglobinuria had suggested that the number and functional capacity of these cells were important factors in the ætiology of the disease. It was therefore thought that splenectomy experiments would help to confirm or contradict this view as well.

Material and technique

In all 118 monkeys belonging to three species (*Silenus rhesus*, *S. irus* and *S. radiatus*) were studied. This number includes 75 monkeys

already reported upon by the senior writer (Krishnan *et al.*, 1933). Observations were made on the incidence of malarial hæmoglobinuria in all these monkeys which were composed of 56 splenectomized monkeys and 62 non-splenectomized monkeys. The operation of splenectomy was done in the same manner as reported previously (Krishnan *et al.*, 1933). Approximately half the number of animals in the splenectomized and non-splenectomized groups were given specific treatment with quinine when the infection reached a definite intensity. The results are presented in table I.

TABLE I

Showing the incidence of malarial hæmoglobinuria in splenectomized and non-splenectomized monkeys

Species of monkey	NON-SPLENECTOMIZED GROUP		SPLENECTOMIZED GROUP		
	Total number	Number showing hæmoglobinuria	Total number	Number showing hæmoglobinuria	
<i>S. rhesus</i> {	Untreated	11	4	10	9
	Treated	25	4	16	7
Total ..		36	8	26	16
<i>S. irus</i> {	Untreated	12	0	12	5
	Treated	6	0	10	1
Total ..		18	0	22	6
<i>S. radiatus</i> {	Untreated	4	0	4	2
	Treated	4	0	4	0
Total		8	0	8	2
Mixed Total		62	8	56	24

From the above table it will be evident that the incidence of hæmoglobinuria is significantly higher in the splenectomized than in the non-splenectomized group. In *irus* and *radiatus* monkeys which do not show any hæmoglobinuria in the non-splenectomized state, hæmoglobinuria occurs in the splenectomized state. Treatment with quinine reduces the incidence of hæmoglobinuria in all cases but does not prevent it. In the *rhesus* monkeys the fall is not very marked being only one-half in both splenectomized and non-splenectomized groups; but in the *irus* and

radiatus monkeys beneficial effects of treatment are more significant even in the splenectomized group. This difference between the species is probably dependent upon the distribution of the reticulo-endothelial system and upon the powers of mobilization of the factors favouring phagocytosis. In some of our previous papers (Krishnan *et al.*, 1933) we have produced indirect evidence in support of this view. The results of splenectomy therefore vary in different animal species and also in different members of the same species.

Discussion

Here it may be interesting to discuss the bearing that this experiment of splenectomy on monkeys has on the blackwater fever problem in man. The best way to do this is to compare some of the known facts regarding malarial hæmoglobinuria in the monkey with those relating to blackwater fever in man, and from them to draw inferences regarding the factors of importance in the ætiology of these conditions.

From the comparative table it is evident that hæmoglobinuria in the monkey is comparable to blackwater fever in man. The *irus* monkey corresponds to the indigenous population of blackwater areas and the *rhesus* monkey to the non-immune immigrants developing blackwater fever. The freedom from hæmoglobinuria of the *irus* and the indigenous inhabitants, and the tendency of the *rhesus* and the immigrant population to develop the condition frequently, may be explained in terms of host-parasite relationship. In the first case the long association between host and parasite, and the more successful host-parasite adjustments lead to less severe disease and less frequent hæmoglobinuria, and in the second case the shorter association and the less successful adjustments lead to more severe disease and more frequent hæmoglobinuria. In both man and monkey the condition appears to be definitely associated with malaria, damaged reticulo-endothelial system and functional failure of phagocytes. The evidence on the whole stresses the prime importance of host immunity; the species and virulence of the parasite comes only second (Giglioli, 1932).

If the above inference is correct the question naturally arises what is the nature of this immunity, or its converse susceptibility, so far as malarial hæmoglobinuria is concerned, and what factor or factors determine their increase or decrease? In several of our previous papers (Krishnan *et al.*, 1932-33) we presented evidence to show that the reticulo-endothelial system plays a very important part in the cure of malaria and that damage or dysfunction of the system increases the severity of malaria and lessens the efficacy of specific drugs. In this article we have shown that the removal

Table of comparison

Hæmoglobinuria in monkey	Blackwater fever in man
<ol style="list-style-type: none"> 1. This is caused by <i>P. knowlesi</i> which is a natural parasite of the monkey, <i>S. irus</i>. 2. <i>P. knowlesi</i> causes no hæmoglobinuria ordinarily in <i>S. irus</i> but merely gives rise to a mild low-grade infection which has a tendency to spontaneous recovery. 3. <i>P. knowlesi</i>, when inoculated into a different species of monkey (<i>S. rhesus</i>) living in a different locality (India) where infection with this plasmodium is unknown, commonly gives rise to an intense infection, hæmoglobinuria and death. 4. Malarial parasites other than <i>P. knowlesi</i> are also known to cause hæmoglobinuria under conditions of lowered resistance. <i>P. inui</i> and <i>P. kochi</i> in splenectomized animals produce hæmoglobinuria. 5. Intense infections are often associated with hæmoglobinuria. 6. Splenectomy increases the incidence of hæmoglobinuria in all species of monkeys. 7. The <i>irus</i> and <i>radiatus</i> monkeys which do not develop hæmoglobinuria under ordinary conditions get it after splenectomy, which is a recognized method of damaging the reticulo-endothelial system and of increasing susceptibility. 8. The results of treatment of hæmoglobinuria with quinine have varied according to the resistance of the animal species to malaria, i.e., they are best in the resistant <i>irus</i> and worst in the susceptible <i>rhesus</i>. Lowering the resistance through splenectomy reduces cure rate. 	<ol style="list-style-type: none"> 1. This is commonly associated with <i>P. falciparum</i>, a natural parasite of man residing in, hyperendemic malarial areas. 2. <i>P. falciparum</i> does not ordinarily cause blackwater fever in the resistant indigenous population of these areas but merely gives rise to malarial attacks of moderate to low severity. 3. <i>P. falciparum</i> infection acquired by people of non-malarious areas living in a blackwater country gives rise to severe disease which after varying periods of time is often followed by blackwater fever. 4. In a certain percentage of blackwater fever cases (about 5 to 10 per cent) <i>P. vivax</i> and <i>P. malariae</i> have been found and considered to be responsible for the disease. 5. Blackwater fever is not associated with a high parasitization. (Man gets treated and keeps down the infection.) 6. Repeated attacks of malaria, irregular dosage with anti-malarial drugs specially quinine, and long-continued residence in a hyperendemic malarial area, jointly produce a condition, in a small percentage of persons, similar to experimental splenectomy and increase susceptibility to blackwater fever. 7. Some of the indigenous population of blackwater areas sometimes get the disease when their susceptibility is lowered. The higher incidence in the indigenous children, who are relatively more susceptible than the adults, stresses the importance of host susceptibility. 8. Treatment of blackwater fever is still unsatisfactory. The cure rate is higher in the more resistant indigenous population than in the non-immune immigrants residing in blackwater areas.

of the spleen increases the incidence of hæmoglobinuria and decreases the chances of recovery, even after treatment with quinine. It is well known that the spleen is an important storehouse of the reticulo-endothelial system and that one of the recognized functions of this system is the removal of effete red cells and hæmoglobin from the circulation. So when the spleen is removed, the total amount of reticulo-endothelial cells decreases and possibly also other changes (biochemical and physico-chemical) occur that lower the functional capacity of the residual reticulo-endothelial cells. If sudden severe hæmolysis takes place under such a condition the reticulo-endothelial cells are unable to dispose of the hæmoglobin liberated, the concentration of it soon rises and hæmoglobinuria results. This view is supported by the observation that in blackwater fever the hæmolysis is extracellular or outside the reticulo-endothelial system. We have repeatedly observed the absence of proliferation of the reticulo-endothelial cells in hæmoglobinuria and the presence of it in monkeys not developing hæmoglobinuria despite a heavy infection. McNee (1932) has also recorded similar changes in the spleen and liver of one blackwater fever

case that he studied. Another fact that supports this view is the difference in the cure rate after quinine in the splenectomized and non-splenectomized animals. In a previous paper Krishnan (1933) presented evidence that the action of quinine is indirect, through stimulation of the reticulo-endothelial system. Therefore the success of treatment in hæmoglobinuria may be presumed to depend upon the capacity of the drug used to elicit an adequate response from the reticulo-endothelial system and to bring about conditions favourable for phagocytosis. If the drug is administered when the reticulo-endothelial system is damaged, as by splenectomy, then the response elicited will be below par and no appreciable benefit will be seen in most of the cases. This is exactly what is found in the experiment recorded in this paper. Therefore, we suggest that, as the powers of response of the reticulo-endothelial system in hæmoglobinuria are low and as no drug has yet been discovered that can stimulate the reticulo-endothelial system with certainty and also prevent hæmolysis, the results of treatment are unsatisfactory and vary with the natural resistance of the host.

Before closing this discussion it is interesting to refer to one point of difference that exists between hæmoglobinuria in the monkey and blackwater fever in man (*vide* para 5 in comparative table). In the former, the sudden severe hæmolysis that gives rise to hæmoglobinuria is probably caused by the sporulation of the parasites, whereas in the latter the cause of hæmolysis is as yet 'unknown'. In man, during the blackwater state malarial parasites are seldom found in the peripheral blood. They are only seen some time before or a long time after an attack. What then is the factor that causes hæmolysis of red cells? Although it has been established that there exists a definite relationship between blackwater fever and malaria two questions still remain unanswered, namely (a) how does malaria act in producing a condition favourable for blackwater fever, and (b) what brings about the hæmolysis? Regarding (a) we have produced evidence that suggests that malaria acts by damaging the reticulo-endothelial system and by retarding phagocytosis mainly through biochemical changes and with regard to (b) the question is awaiting solution. Is it a hæmolysin? If so, what is its nature and how is it produced?

Summary and conclusions

(1) Removal of the spleen in monkeys infected with *P. knowlesi* intensifies their infection and increases the incidence of hæmoglobinuria.

(2) Treatment of monkeys showing hæmoglobinuria with quinine is unsatisfactory. It is even less effective in splenectomized animals.

(3) The results recorded in this paper stress the importance of susceptibility in hæmoglobinuria and suggest that the spleen and the reticulo-endothelial system play an important part in this susceptibility.

Acknowledgment

We are deeply indebted to Lieut.-Colonel A. D. Stewart, C.I.E., I.M.S., Director, All-India Institute of Hygiene and Public Health, Calcutta, for his interest in this work and for the valuable suggestions and criticisms received from time to time.

A PRELIMINARY NOTE ON THE CULTIVATION OF VACCINIA VIRUS ON THE CHORIO-ALLANTOIC MEMBRANE OF CHICK EMBRYO

By K. S. SHAH, D.Sc., M.B., B.S., D.P.H., D.T.M.

Additional Superintendent, Punjab Vaccine Institute
Lahore

(Punjab Public Health Department)

ALTHOUGH vaccinia virus has been propagated for centuries on the skin of healthy animals for Jennerian prophylaxis in man, its true nature is still under the cover of mystery. In the literature of the past, it is not uncommon to encounter reports in which it was claimed that vaccinia virus had been successfully cultivated on lifeless media. These reports have not been confirmed and at present such claims are rarely made.

Whereas the cultivation of vaccinia virus in lifeless media has so far not been accomplished, this agent has been cultivated by Haagen (1928), Li and Rivers (1930), Maitland and Laing (1930) and others in the presence of tissues surviving *in vitro*. Goodpasture and Woodruff (1932) in collaboration with Buddingh described a method of cultivating vaccinia virus on the chorio-allantoic membrane of chick embryo. Using the same method with certain modifications Stevenson and Butler (1933) were able to infect a large proportion of suitable eggs with vaccinia virus.

An attempt was made to cultivate vaccinia virus on the same lines at the Punjab Vaccine Institute, Lahore. The work is still in progress, this being only a preliminary note dealing with the technique, and the progress that has so far been made with the experiments.

Materials and methods

Goodpasture and Woodruff had ordinarily used bacteria-free virus in fresh infected rabbits' testes (Levaditi's neuro-vaccine) to initiate the infection. Stevenson had used a dermal strain derived from the papule on the skin of a rabbit.

The writer has used the ordinary glycerinated buffalo calf lymph to initiate the infection

on the eggs. This 'seed lymph' although free from pathogenic organisms was far from being sterile.

Method

Hens' eggs supposed to be fertile were incubated in an ordinary chicken incubator for 10 to 12 days. The eggs were then candled to locate the embryo and air sac. Eggs containing dead or undeveloped embryos were discarded and only those containing live embryos were used. Each of these was ringed with a coloured pencil. The surface of the shell overlying the embryo was carefully cleansed with methylated spirit and flamed with a piece of burning cotton-wool. Flaming the area did not kill the embryo. All instruments were dipped in alcohol and flamed. By means of a sharp pointed knife a hole was bored through the shell and the shell membrane, thus exposing the extra-embryonic membrane, which often got damaged in the process, as evidenced by a slight trace of blood. The trauma, however, did not kill the embryo. A small quantity of the inoculum (calf lymph) was drawn up into a sterile fine capillary pipette and injected through the hole on to the surface of the chorio-allantoic membrane. The hole was then closed with melted paraffin, and the egg returned to the incubator. Incubation was continued for four days, after which the egg was opened (figure 1). Before opening, the shell was cleansed

chorio-allantoic membrane exposed. This was incised and the contents within the membrane were drawn out with forceps, leaving the membrane attached with the shell. The membrane was then carefully removed by means of a pair of forceps. In cases in which the growth of the virus had taken place, a vesicle was found on the membrane at the point of inoculation (figure 2). The vesicle was cut off with a pair of scissors. It was weighed and ground in a

Fig. 2—A vesicle is seen on the membrane.

Fig. 1—An egg has been opened.

with methylated spirit and flamed, so that the surface of the shell was aseptic. The shell and the shell membrane were then broken and the

sterilized pestle and mortar with four times its weight of 50 per cent glycerine. The mixture was stored in an ice-chest at about 40°F and was later tested for bacterial contamination and also for determining the potency of the lymph on rabbits and human beings.

Observations

The experiments were started in August 1934, and the seed lymph (buffalo calf lymph) has so far been carried on to four generations on chick embryos in succession—

$B \longrightarrow C_1 \longrightarrow C_2 \longrightarrow C_3 \longrightarrow C_4$

B = Buffalo calf vaccine lymph, small amount.

C_1, C_2, C_3 and C_4 = First, second, third and fourth generations of vaccine lymph on the membrane of chick embryos

The average yield from each egg has been 0.4 gramme and when diluted with four times its weight of 50 per cent glycerine has been sufficient to vaccinate 100 children with four insertions each. Attempts are being made to increase the yield by inoculating the embryo at more than one place and two, three and four vesicles have been obtained from a single egg without jeopardizing the life of the embryo. Samples from each of the four generations of chick-embryo vaccine lymph were tested for

TABLE

TABLE

A HYGIENIC METHOD OF COMPOSTING REFUSE WITH NIGHT-SOIL

By J. J. RAO

and

V. SUBRAHMANYAN

Department of Biochemistry, Indian Institute of Science, Bangalore

UTILIZATION of all forms of organic waste including human excreta as manure has been a recognized item of agricultural practice in China and Japan for over four thousand years. The preparation of 'mud' composts (King, 1911) and the fermentation of night-soil in cisterns for direct application to fields are also of ancient origin in those countries though the scientific and sanitary aspects of the related processes were not investigated until recent years.

In many parts of India, it has long been the practice to utilize night-soil as manure without any previous treatment. It is also occasionally used for preparing 'poudrette' in combination with mud and refuse. In recent

years, however, the desirability of preparing composts from night-soil and different forms of organic wastes under aerobic conditions is being increasingly realized as efficient means of both disposal and utilization of such materials. Fowler (1927) suggested that night-soil might be dumped on refuse heaps and the mixture turned frequently so as to facilitate aeration. In a later publication he summarized the results of experiments in which night-soil was used both as a source of nitrogen and as a biological starter for the preparation of compost. Rao and Subrahmanyam (1932) conducted experiments with fresh as well as liquefied night-soil and found the latter to be cleaner and more convenient to handle than the former. Based on the previous work of Howard and Wad (1931) a method of disposing of municipal wastes has been worked out by Jackson and Wad (1932) on a big scale at Indore. Composting on a large scale is also in progress at Mysore and has been described by Mieldazis (1934).

Although much useful work has already been done in India alone, there are still various aspects of the problem which require elucidation. The present enquiry was undertaken therefore with the object of further standardizing the conditions so as to (a) prevent fly-breeding, (b) maintain high temperature in the compost heap, and thus kill out putrefactive and pathogenic organisms, (c) reduce the loss of nitrogen which invariably accompanies heavy applications of night-soil, (d) restrict the profuse decomposition of organic matter and improve the yield of the finished product, and (e) ensure maximum availability of the fertilizing ingredients present in the different components.

Experimental

Treatment of refuse with fresh diluted night-soil.—Three heaps (nos. 1 to 3) of refuse each 6 feet by 6 feet at the base, 6 feet by 4 feet at the top, and 2 feet high were made. Each heap contained 5 cart-loads of town

refuse, and the contents of each cart weighed from a quarter to one-third of a ton. The suspension of night-soil was prepared as follows. To about 15 gallons of freshly collected night-soil contained in a small drum attached to a hand cart, thrice the volume of sewage (septic-tank) effluent was added and the contents stirred together with wooden rods. As far as possible, the bigger lumps were also broken. The suspension which still contained leaves (originally used for clearing pit latrines) and other foreign bodies was applied as such to the three heaps, the contents of one drum being used for each heap. The heaps were opened longitudinally at the centre and the suspension distributed evenly along the sides of the gap thus created. The sides were then drawn in by means of manure forks, and the interior containing the night-soil carefully covered up. The surface of the heaps was kept moist from time to time by application of septic-tank effluent. At the end of one week, heaps 2 and 3 were again opened up and treated similarly with night-soil. At the end of the second week, only heap 3 received a third treatment of night-soil. All the heaps were turned once in every week. The temperature of the heaps was taken every day and was found to range from 40°C. to 50°C. for the first two weeks. Subsequently it came down to below 40°C. Except in heap 1 to which only one cart of night-soil was added, there were innumerable fly-larvæ after the first week. On opening heaps 2 and 3 it was also found that the added night-soil remained practically undecomposed while in heap 1 none of it could be seen. These observations would suggest that the fly-breeding observed in heaps 2 and 3 is due to the presence of undecomposed night-soil.

At the end of 10 weeks, when the decomposition was apparently complete, the heaps were sampled and analysed for nitrogen and ash according to Association of Official Agricultural Chemists (1930) methods (table I).

TABLE I

Heap number	PERCENTAGES		
	Total nitrogen	Ash	
1	.. 0.75	82.0	
2	.. 0.84	87.3	
3	.. 1.18	83.3	

The above experiments were subsequently extended adding 4 and 5 cart-loads of night-soil, but it was found that the nitrogen content remained practically the same (1.2 per cent). This would suggest that the nitrogen added in the later stages was almost entirely lost.

Composting with alternate layers of refuse and night-soil.—Three beds of refuse each 6 feet long, 3 feet wide and 3 inches high were prepared. One cart-load of night-soil was spread on each bed. This was covered by a layer of refuse 3 inches high over which another cart-load of night-soil was distributed. In this manner six alternating layers of refuse and night-soil were made up in each case and the entire heaps finally covered with thin layers of refuse. Septic-tank effluent was then sprayed on the surface of the heaps to maintain the moisture and to facilitate the fermentation. It was soon found however that the entire mass became hard and compact so that the effluent could not penetrate into the heaps.

The fermentation was also slow and the temperature ranged between 40°C. and 50°C. On opening the heaps it was found that the night-soil remained largely undecomposed. There was a highly offensive odour and profuse fly-breeding after one week. Even heavy applications of lime, borax or Bordeaux mixture did not improve the condition of the heaps.

Since undecomposed night-soil occurred mostly in the form of lumps, it was considered desirable that some device should be adopted to break up such lumps and then to apply the night-soil in the form of an emulsion.

Experiments with liquefied night-soil.—It is a well-known Chinese method to dump night-soil into a well or cistern and allow it to undergo spontaneous fermentation prior to application to land. The previous observations of Rao and Subrahmanyam (1932) also show that night-soil stored for even a few days undergoes liquefaction and after suitable dilution can be successfully used for treating refuse heaps. Some further experiments with liquefied night-soil were therefore carried out.

A cylindrical drum, capacity 40 gallons, was fitted up at the bottom with an iron pipe 6 inches long and 1½ inches in diameter. The pipe was provided with a valve and a hose. Night-soil, admixed with leaves and other foreign bodies, was introduced into the drum and stirred with thrice its volume of septic-tank effluent. The drum was then tightly closed with a lid. The contents of the drum were examined from time to time but otherwise left undisturbed for 10 days. It was observed that in the beginning there was frothing accompanied by the formation of a scum at the surface. In the later stages the fermentation became very much more vigorous and the liquid mass appeared as though it was boiling. After 10 days, the reaction subsided and a homogeneous brownish-yellow liquid was obtained. The leaves present along with the night-soil did not undergo fermentation but were found either floating at the surface or submerged in the emulsion. To treat refuse heaps, the emulsion was drawn through the hose by opening the valve of the outlet pipe. After the major part of the liquid had been drawn, fresh night-soil was added to the drum and again mixed with thrice its volume of septic-tank effluent. It was found on this occasion that the fermentation started very much more vigorously than before and that the liquefaction of the freshly added night-soil was complete within 72 hours. With repetition of this treatment, it was found that an increasingly active mass of liquefying organisms had been set up in the drum with the result that, in the later stages, the liquefaction was often complete within 24 hours. The undecomposed leaves were removed periodically using manure forks. Large quantities of night-soil were liquefied in this manner and used for treating refuse heaps.

Mode of heaping; importance of loose packing in the early stages.—It is well known that the maintenance of high temperature of the order of 50°C. for at least 24 hours is necessary in order to destroy weeds and pathogenic organisms. The thermal death point of many organisms varies from 50°C. to 60°C. within which range they are killed out if exposed for even a few minutes. Thus, *B. typhosus* is killed in about 7 minutes at 55°C. If the temperature is lowered by 7 or 8-degrees, it may take several

hours before all the cells are killed out. It is desirable therefore that in the compost heap, a high temperature (above 50°C.) be attained although only for a short period. The most favourable condition for a rise in temperature is provided by loose packing which ensures an adequate air supply for the active functioning of the thermophilic bacteria and fungi which are responsible for the fermentation. The importance of this principle is realized in the 'Edelmist' process developed by Kranz in Germany. The 'Beccari' process adopted in Italy consists in decomposing organic materials in closed cells provided with ventilation. According to that method, a temperature of 140°F. was recorded (Smith, 1924). In view of the above and other observations the heaps prepared for subsequent experiments were always packed loosely.

Removal of non-organic matter.—The collections of refuse from a town contain large amounts of non-organic matter such as stones, gravel, glass and tin which should be removed before any treatment is given. This is easily done by dumping the refuse at a place in long rows about 3 feet high and 3 feet wide at the base and then dragging the refuse by means of manure forks. Heavy materials like sand and stones are thus left behind. Lighter or smaller ones like pieces of glass or tin are picked up by hand and thrown away.

Composting with liquefied night-soil.—Four heaps (nos. 4, 5, 6 and 7) each measuring 6 feet long, 3 feet wide and 3 feet high were made. The materials were left loose and no attempt was made to press the heaps during the formation. The top of each heap was also covered loosely with refuse keeping it in the form of a dome.

The night-soil emulsion was applied as follows:—The top layer of refuse was drawn aside by manure forks, keeping it all along the length of the heaps so that the flat surface was visible. Night-soil emulsion was then sprayed all over the surface of the heaps, wetting the material inside. Care was taken, however, not to add an excess which would soak down to the earth. For each heap of the size mentioned above, 8 gallons of emulsion were required for treatment on the first day. From the second day up to the eighth day 5 gallons per day were added and later up to the twenty-fifth day 4 gallons of emulsion per day were sprayed.

It was observed that within 24 hours of the first treatment there was rapid fermentation, the temperature rising to 52°C. Before the end of one week it had risen to 60°C. At the end of the week the heaps were turned so as to facilitate aeration and hence keep up the high temperature. The heaps were treated again with the emulsion in the same manner and turned every week. After twenty-five days the temperature gradually came to 45°C. and then to 40°C. and later still to that of the atmosphere (21°C. to 26°C.). There was no fly-breeding in any of the heaps.

On the twenty-sixth day the treatment of heaps 4 and 5 was stopped while that of heaps 6 and 7 was continued until the sixtieth day in spite of the fact that the temperature did not show any rise. At the end of that period, the resulting manure was sieved through a half-inch-meshed expanded-metal screen, and analysed for total nitrogen.

TABLE II

Heap number	Total nitrogen, per cent
4	0.61
5	0.57
6	0.73
7	0.67

The nitrogen content was comparatively low in all the cases. Even prolonged application of night-soil for sixty days did not appreciably improve the nitrogen content, thereby showing that a considerable part of the added nitrogen was lost.

In view of the probable error introduced by parallel heaps not fermenting at the same rates, the experiments were next repeated as follows:—

One big heap was treated with liquefied night-soil in the manner already described; after twenty-five days, the heap was divided into two (heaps 8 and 9). Heap 8 was sprayed with tap water and heap 9 with night-soil emulsion. After sixty days the resulting manures were sieved and the nitrogen and degree of humidification (Jones, 1927) estimated.

TABLE III

Heap number	Total nitrogen	Organic matter	Humidification
P e r c e n t a g e s			
8	0.69	26.2	73.5
9	0.77	23.1	72.2

These observations confirm the previous results and show that after twenty-five days the addition of night-soil may be stopped from both the point of view of sanitation and nitrogen conservation.

Changes in reaction and nitrogen content during liquefaction of night-soil and aeration of the liquefied product.—The night-soil was macerated with thrice its volume of tap water and the supernatant liquid decanted into a five-litre bottle. After determining the nitrogen content of a representative sample, the residue was left for ten days in the stoppered bottle to undergo liquefaction. After that period it was found that the volume of the liquefied product had not changed appreciably. The nitrogen content of the fresh suspension was 81.8 parts per 100,000 while that of the final product was 82.8 parts, thereby showing that there was no appreciable change during liquefaction.

An experiment was next carried out with night-soil diluted to about half the previous concentration in order to follow at daily intervals the H-ion concentration colorimetrically. The results (table IV) show that, with the progress of liquefaction, the reaction tended to become less acid.

TABLE IV

Days	pH	Days	pH
1	.. 6.8	6	7.4
2	.. 6.8	7	7.4
3	.. 7.0	8	7.4
4	.. 7.4	9	7.4
5	.. 7.4	10	7.6

It appeared probable that the change in reaction was due to production of ammonia,

accordingly some trials were carried out adding sodium carbonate (5 g.) to 150 c.cm. of liquefied night-soil emulsion containing 44.8 parts of nitrogen per 100,000 and aerating the mixture. The gases were drawn through dilute mineral acid and, ammonia thus absorbed, they estimated by back-titration (table V).

TABLE V

Time of aeration in hours	Ammoniacal nitrogen, as parts per 100,000	Time of aeration in hours	Ammoniacal nitrogen, as parts per 100,000
2	1.5	14	13.8
5	3.0	17	14.7
8	6.6	19	15.9
10	10.8	22	16.5
12	12.6	24	17.4

It may be seen from the above that, with prolonged aeration, increasing quantities of ammonia are formed. This is probably partly due to the action of sodium carbonate on the albuminoids in night-soil, but the results suggest, nevertheless, that considerable quantities of nitrogen may be lost during aeration of the liquefied product by biological oxidation. An analysis of the residue showed that it contained 26.5 parts per 100,000 of nitrogen, so that it may be seen that the difference is almost exclusively due to the removal of ammonia.

Aeration of night-soil on a large scale.—Partly with a view to breaking up big lumps and partly to remove offensive odours, some experiments were carried out aerating night-soil in a macerating tank.

The tank was 35 feet long, 6 feet wide and 7 feet deep and divided into two compartments one of which had slightly over three times the capacity of the other. The bigger compartment was first half-filled with sewage effluent after which forty cart-loads of night-soil were tilted in and the mixture stirred up. After the mass had liquefied, compressed air was sent in through diffusers fitted at the bottom of the tank and the mass kept well agitated. The aeration was stopped after three hours and the suspension allowed to stand undisturbed. After twenty-four hours, fresh sewage effluent was added to make up for any change in volume. The aeration was then resumed and continued for a further period of three hours. The treatment was thus continued for some time and samples examined at intervals. For chemical analysis, the samples were collected at the same spot and at a time when the liquid was being aerated, so that there was thorough stirring of the liquid during sampling.

Total nitrogen was estimated by the Kjeldahl method, total solids by evaporation at 100° and oxygen absorption (4 hours) by determining the unused permanganate in the usual way. The results have been presented in table VI.

TABLE VI

Time in hrs.	Total solids, p. p. 100,000	Oxygen absorbed (4 hours), p. p. 100,000	Total nitrogen, as gms. per gallon	Loss of nitrogen, per cent
0	4,050	204.6	8.4	..
15	3,300	147.6	6.8	19.0
36	3,450	172.2	6.8	19.0
57	3,350	206.4	6.7	20.0
78	3,300	179.7	6.2	26.2

It was observed that after 15 hours the suspension had turned brownish-black and was almost odourless.

There was a marked decrease in total solids, oxygen absorption and total nitrogen. After that period there was not much change in total solids. The oxygen absorption showed a tendency to increase while total nitrogen showed further decrease.

The foregoing observations indicate the type of changes that are consequent on intermittent aeration of night-soil. The treatment represents a short period of aerobic condition followed by a long one of inadequate air-supply during which night-soil might partially revert to the septic condition. The results show that considerable loss of nitrogen will occur under such conditions.

Vegetation experiments with manure prepared out of refuse and liquefied night-soil.—Experimental pots were prepared in the usual way by mixing one part of sand with three of soil and the mixture (30 lbs.) treated with lime at 20 g. per pot. After about a week the following manures were applied on an equivalent nitrogen basis. (a) Farm-yard manure (N=0.31 per cent) at 72.5 g., (b) compost treated with night-soil emulsion for 25 days at 36.5 g. and (c) compost treated with night-soil for 60 days at 30.2 g. per pot, respectively. Two crops, ragi (*Eleusine coracana*) and barley, were raised. When the grains were ripe, the plants were carefully removed and the weights of grain, straw and roots determined. The results are given in table VII.

TABLE VII

Manure	Dry weights in grams		
	Grain	Straw	Roots
Experiments with ragi (average weight of 10 plants in each case)			
Farm-yard manure (a)	0.18	0.94	0.39
Compost (b)	.. 0.17	0.90	0.35
" (c)	.. 0.29	1.43	0.61
Experiments with barley (average of 9 plants in each case)			
Compost (b)	.. 0.16	0.27	0.04
" (c)	.. 0.13	0.25	0.04

It may be seen from the above that, in the case of ragi, refuse treated with night-soil for 25 days yielded a product which, on an equivalent nitrogen basis, is nearly as good as farm-yard manure while treatment for 60 days yielded a much better product. This conclusion is not supported however by observations on barley which responded better to manure prepared after treatment for 25 days than to one receiving treatment for 60 days. This apparent discordance between the two sets of observations is presumably due to some difference in the nutritional requirements, and also the duration of the two crops. Further work is in progress to throw more light on this aspect of the problem.

Discussion

The results of the present enquiry have brought out some facts of practical interest and have indicated certain useful lines of future work.

The earlier experiments have shown that application of large quantities of fresh night-soil is not only unnecessary but also undesirable. After the second week, the rate of decomposition slackens and the temperature fails to rise above 40°C. with the result that fly-breeding proceeds unchecked. The heaps also

begin to emit unpleasant odours so that it becomes necessary either to reduce the quantity of night-soil or to subject it to some pre-treatment, which would render it possible to compost large quantities of night-soil with limited amounts of refuse.

Although it has been suggested by us in a previous communication that different forms of waste vegetation can be used to supplement town refuse, it is not generally possible to command such facilities. Even if there are jungles in the neighbourhood, the cost of collecting and transporting the materials may be so considerable that it may not pay to prepare compost out of them. An alternative scheme would be to grow the required vegetation and to use it, on the spot, for composting. This again is not generally feasible because most municipalities cannot find the space required for the purpose. Even if some land were available, it would be hardly practicable to raise fresh vegetation for composting in preference to market-garden and fodder crops which bring ready cash. It would be necessary therefore to devise other means to facilitate the composting of night-soil with town refuse only.

The experiments with liquefied night-soil have shown that large quantities of that product can be successfully applied at daily intervals for a period of 25 days. A high temperature (50°C. to 60°C.) is maintained throughout that period, so that there is no fly-breeding or danger of pathogenic or putrefactive organisms persisting under such conditions. The process of liquefaction proceeds spontaneously and requires no special attention. The liquefied product can be more easily diluted and is generally more convenient to handle than fresh night-soil. There is, no doubt, some smell especially at the time of removing the liquefied night-soil from the cistern, but the heaps composted with that product do not emit such offensive odours as those treated with the fresh material. It will be seen therefore that, from the sanitary point of view, the liquefied product is far more satisfactory to work with than the fresh material.

The experiments on aerating night-soil have shown that, although it is a useful method of removing offensive odours, it is nevertheless wasteful as it leads to loss of nitrogen as ammonia; this treatment would therefore appear to be undesirable. A similar observation would also apply to continued treatment of refuse heaps with liquefied night-soil for even 25 days since it results in persistently high temperature and considerable loss of nitrogen. The resulting composts are very much poorer in nitrogen than those reported according to the Edelmist or the Beccari processes (*loc. cit.*). It is desirable therefore that the number of applications of night-soil should be reduced and the fermentation in the loosely-packed heap allowed to

proceed for just the minimum period of time required to kill out weeds, seeds and insect larvæ. The subsequent fermentation should be so controlled that the loss of nitrogen is reduced to a minimum. Further work in this direction is in progress.

Summary

(1) Heavy applications of fresh night-soil at weekly intervals result in the slackening of fermentation after one week. The temperature does not rise above 40°C. and fly-breeding proceeds unchecked. After three weeks, the added nitrogen is also mostly lost.

(2) Composting with alternate layers of refuse and night-soil is undesirable as it leads to the hardening of the mass and consequent slackening in fermentation.

(3) Liquefaction of night-soil by spontaneous fermentation has been found to be a convenient way of breaking up big lumps and eliminating other associated waste materials. The details relating to the liquefaction of night-soil and its application to refuse heaps have been described.

(4) During liquefaction, the reaction of night-soil tends to become slightly alkaline. There is no significant change in the total nitrogen content.

(5) Liquefied night-soil can be applied to refuse heaps continuously for a period of 25 days. During the major part of that period the temperature of the heap ranges between 50°C. and 60°C. Application of night-soil after that period is undesirable as the temperature tends to fall below 40°C.

(6) Aeration of liquefied night-soil leads to loss of nitrogen as ammonia. Attempts to macerate night-soil by intermittent aeration also leads to considerable loss of nitrogen.

(7) Pot-culture experiments with ragi (*Eleusine coracana*) and barley have shown that, when considered on an equivalent nitrogen basis, the compost prepared out of liquefied night-soil and refuse is at least as efficient as farm-yard manure.

The authors' thanks are due to the Mysore Compost Committee for kindly providing the necessary facilities for some of the field experiments.

THE VALUE OF PHRENIC EXAIRESIS IN THE TREATMENT OF PULMONARY TUBERCULOSIS

By P. V. BENJAMIN, M.B., B.S. (Madras)
T.D.B. (Wales)

Acting Medical Superintendent, Union Mission Tuberculosis Sanatorium, Arogyavaram, near Madanapalle

PHRENIC EXAIRESIS, or phrenicectomy as it is now commonly called, is one of the widely-used operations in the treatment of pulmonary tuberculosis. A review of the first 104 cases done at the Union Mission Tuberculosis Sanatorium was published five years ago (Frimodt-Møller and Gnanamuthu, 1930). It is now possible to review 275 cases of phrenicectomy.

The operation and its technique

In 1911, Stuertz suggested phrenicectomy, or the mere cutting of the phrenic nerve, as a method in the treatment of unilateral pulmonary tuberculosis. The results of this operation were often disappointing. The credit for the present-day success of the phrenic operation is due to Felix. He proposed the operation of phrenic exairesis, or the evulsion of the complete nerve. By this operation the continuity of the main nerve and all its branches was destroyed. Goetze, fearing the danger of tearing important structures during the evulsion, proposed an alternative method. This method consisted of the resection of a part only of the main trunk along with the resection of a part of the accessory phrenic nerve or nerves.

The phrenic nerve usually arises from the third and fourth cervical roots; additional fibres may come from the fifth also. The nerve crosses the anterior scalene muscle in an oblique direction from above downwards and inwards. Throughout the greater part of its cervical course, the nerve usually lies on the anterior surface of the anterior scalene muscle. It may cross the muscle at a high level and then the nerve is found in the medial aspect of the muscle; very occasionally the nerve is in very close apposition to the brachial plexus and then it may lie on the lateral aspect of the muscle and may cross it only at the point of insertion of the muscle. The accessory fibres to the phrenic nerve follow the first part of the brachial plexus taking their origin usually from the fifth or sixth cervical roots. They may arise as a single bundle or as a series of 2 or 3 nerves, which run obliquely downwards and inwards from the brachial plexus joining the main trunk of the phrenic nerve occasionally in the neck but more often below the level of the clavicle (Morriston-Davies, 1933).

Sometimes the phrenic nerve may be found to be bound down by adhesions and it may not be possible to evulse the whole nerve. In such cases it is dangerous to pull it violently. Our technique usually is to expose the nerve in the neck, dissect it out free from under the fascia

of the anterior scalene muscle and then use slow traction. If the nerve comes easily, the whole nerve is evulsed. If there is considerable resistance, no attempt is made to evulse the whole nerve but as much of the nerve as can be pulled out is cut off. When two or three inches of the nerve are pulled out, the diaphragmatic pull can usually be felt. In our experience if this pull is felt clearly we can expect a complete paralysis of the diaphragm, even though only a small portion of the nerve is removed and the accessory phrenic nerves are not dissected out. When the diaphragmatic pull is not clearly felt, and if the nerve breaks off, or if it has to be cut off, the accessory nerves have to be searched for and cut. In our series of cases, of those which were controlled by fluoroscopic examination only six showed incomplete or no paralysis of the diaphragm. In 5 of these the nerve broke off before the diaphragmatic pull was felt and no accessory phrenic nerve could be identified; in the other the nerve was only crushed.

The actual length of nerve removed is of little consequence provided the diaphragmatic pull is clearly felt before removal. In twenty-five cases the whole nerve measuring from 10 to 13 inches was evulsed, but in the majority from 4 to 9 inches only of the nerve were removed, while in a few even less than one inch. The average length of nerve removed was $4\frac{1}{2}$ inches; but there was no correlation between the amount of the nerve removed and the paralysis of the diaphragm as shown by the x-ray examination.

Complications

Complications met with during the operation in our earlier series of 104 cases were dealt with in our previous paper. They were injury to the internal jugular vein in one case, rupture of the dome of the pleura in another, and vomiting and shivering in a few. In the last 171 cases we have met with no complications.

Effect of phrenic evulsion

The phrenic and accessory phrenic nerves are solely responsible for the motor supply of the diaphragm. Phrenic evulsion produces a complete paralysis of the corresponding dome of the diaphragm. The muscle fibres of the diaphragm gradually atrophy and the dome in course of time is converted into a parchment-like membrane (Stanbury, 1934). The paralysis of the diaphragm is usually followed by a rise of the diaphragm in the side operated upon. The height to which the dome will rise in any particular case cannot be foretold. In some there may be no immediate rise, but it may be found three months or a year later. Pleural adhesions are one of the factors that affect the rise of the diaphragm, but this rise does not always depend upon pleural adhesions, as in some cases with extensive pleural adhesions the rise of the diaphragm has been found to be

high. Another factor that influences the rise of the diaphragm is the condition of the underlying lung—whether it is yielding or not. When there is extensive infiltrative exudation and the alveoli are filled with exudation, the lung is not easily collapsible and consequently the rise

Fig. 1.—Before phrenic exaeresis.

Fig. 2.—After phrenic exaeresis

of the diaphragm is not likely to be complete. The effect of the rise of the diaphragm is a partial collapse of the lung. This collapse is not necessarily confined to the base of the lung but is distributed throughout the whole lung as it has been observed that cavities in the middle and upper zones of the lung change in shape, size and position. Another effect of the paralysis of the diaphragm is the relaxation of the tension on the lung and also the elimination of the pumping action of the diaphragm.

Indications for the operation

Phrenicectomy can be used as the sole surgical method of treatment or in conjunction with other operative measures. Generally speaking it can be said that the indications for phrenicectomy are the same as for artificial pneumothorax and it is done as the sole surgical method in cases in which pneumothorax has failed because of adhesions. In such cases it is specially recommended for thin-walled cavities with no or only slight surrounding infiltration (Slavin, 1934). Phrenicectomy is often done as a preparatory operation to thoracoplasty. Then the object of the operation is in some cases to test the ability of the contra-lateral lung to stand the major operation, but its value in this connection is doubted by some (Head, 1934). It should be done as a preliminary to localized upper thoracoplasty as the improvement caused by the phrenicectomy may in some cases make the major operation unnecessary or in others it may improve the condition of the patient so much as to make the patient stand the thoracoplasty operation better. Phrenicectomy is also used in some cases of hæmoptysis in which an artificial pneumothorax is impossible and for which a thoracoplasty is contra-indicated. We have had strikingly good results in 3 such cases.

Phrenicectomy can be frequently combined with artificial pneumothorax on the same side when there are adhesions preventing an effective collapse. The closure of adherent cavities by combined artificial pneumothorax and phrenicectomy depends on the fact that phrenicectomy releases one of the two tensions on the lung, the tension of the adhesion to the chest wall and the tension of the diaphragmatic movement, especially when there are adhesions also to the diaphragm. While the diaphragm remains active the tension towards the root of the lung predominates and the lung, suspended between two fixed points, continues to be pulled in two directions, thereby increasing the tension on the walls of the cavities. The result of phrenicectomy is that the tension of the lung towards the root is diminished and the contracting capacity of the adhesions acting in one direction only allows the retraction and healing of the diseased lung (Slavin, 1933).

Phrenicectomy is indicated in some cases before stopping artificial pneumothorax. This is specially so when the lung has been extensively affected before the institution of artificial pneumothorax. In such cases healing is produced by extensive fibrosis and, if such a lung is allowed to re-expand fully into the pleural space, the strain on the fibrosing areas may be harmful. Further the contracting fibrous tissue may cause dragging on the bronchial tubes producing, in course of time, bronchiectasis and also possibly extensive retraction of the mediastinum with attendant symptoms, such as pain, tachycardia and irritant cough. In such cases

a preliminary phrenicectomy before stopping artificial pneumothorax diminishes the space into which the healed lung has to expand and thereby prevents or minimizes the troubles mentioned above. In our series of cases phrenicectomy has been done in 30 cases before stopping artificial pneumothorax.

Phrenicectomy may be a useful procedure in some cases to relieve symptoms such as dragging pain, irritating cough and tachycardia. In pulmonary tuberculosis frequently there are adhesions between the pleura, the lung and the diaphragm, and sometimes between the pericardium and the diaphragm; the fibrous tissue contracts and pulls on the surrounding structures causing troublesome symptoms which can in many cases be abolished or relieved by paralyzing the dome of the diaphragm on the affected side.

In certain cases of bilateral affections artificial pneumothorax on the one side and phrenicectomy for the affection of the opposite lung is advocated. A few authors report good results. In our series we had 3 such cases which had pneumothorax on one side and phrenicectomy on the other. None of these three cases improved and we consider the scope for this combined treatment is limited.

Contra-indications.—Phrenicectomy is definitely contra-indicated in cases with chronic bronchitis or asthma and also when extensive fibrosis with emphysema is present.

The value of phrenic evulsion

In judging the value of phrenic evulsion in pulmonary tuberculosis several factors have to be taken into consideration. The disease is a chronic one and rapid improvement cannot always be expected. As phrenicectomy aims at producing a partial collapse of the lung only, it is often unable to effect the dramatic disappearance of symptoms such as can be seen at times when a diseased lung is completely collapsed by artificial pneumothorax. Though the paralysis of the diaphragm immediately follows phrenicectomy, its rise and the consequent collapse of the lung is not always complete immediately after the operation. It has been already mentioned that it sometimes takes 3 to 12 months before the rise is complete.

The presence or absence of disease in the contra-lateral lung is another factor that influences the result. In assessing the value of phrenicectomy, we must also take into consideration with what object in view the operation was done—whether the arrest of the disease was expected or whether the operation was done mainly to relieve symptoms, such as pain, irritating cough or persistent hæmoptysis.

In this connection it is necessary to emphasize that a paralysis of the hemi-diaphragm by phrenicectomy is only an accessory aid in the treatment of pulmonary tuberculosis. Treatment on sanatorium lines is essential.

Phrenicectomy, as all other methods of collapse therapy, is to assist the sanatorium treatment mainly by helping to overcome those mechanical conditions which are a hindrance to improvement. The after-results of phrenicectomy on patients treated at Rists Hospital, Paris, are worth quoting. Of the 100 patients who improved after phrenicectomy 79 had, in addition, sanatorium treatment and this group had 38 patients who obtained permanent good results as compared with only 4 out of 21 who did not receive sanatorium treatment. The conclusion drawn from this is that unless the early benefit of phrenicectomy can be supplemented by the systematic rest and continuous medical supervision of the sanatorium, it is not likely to be maintained.

Analysis of results

Phrenic exairesis operations to the number of 275 have been done at the Union Mission Tuberculosis Sanatorium, Madanapalle, up to 1st September, 1934. Of these, 54 cases are excluded from detailed consideration, as 11 had the operation done as a preliminary to thoracoplasty, 30 had it done after artificial pneumothorax just before leaving the sanatorium, 4 had the operation done for non-tuberculous conditions of the lung, 3 had the operation done combined with artificial pneumothorax on the other side, 2 left the sanatorium before completing one month of treatment, 2 are still under treatment having had the operation done only recently, and in 2 no phrenic nerve could be identified.

Out of the 221 cases included for detailed analysis 1 was in stage I, 23 in stage II and 197 in stage III (*vide* Benjamin, 1934). These patients can be divided into two groups, group I comprising those on whom the operation was done as accessory to artificial pneumothorax treatment on the same side, and group II those on whom it was done as the sole surgical procedure.

In group I there were 52 patients and these received phrenicectomy during the course of artificial pneumothorax treatment as they did not derive the full benefit of pneumothorax due to the presence of adhesions. Of these 34 or 65.4 per cent were benefited by the combined treatment, 27 being discharged as 'much improved' and 7 as 'improved'. This is shown in table I.

This figure may be compared with the figure for the positive results of patients treated at the sanatorium with artificial pneumothorax before the introduction of phrenicectomy. Of 142 patients 66, or 46.5 per cent, obtained positive results. That of a group of 52 patients in whom adhesions prevented a satisfactory collapse in artificial pneumothorax and in whom therefore poorer results might be expected, yet 34 or 65.4 per cent gained improvement is good evidence of the value of phrenicectomy in such patients. It may be mentioned that only

eradicated malaria, whereas quinine had failed even by injections. His skin showed slight pigmentation of the palms within four days and the urine was positive for atabrin. This continued for about a month. His bowels were very constipated.

Case 2.—H. C., 7 years old, son of a doctor, was anæmic and exhausted by successive attacks of malaria, dengue, influenza and tonsillitis. Had still, despite quinine, benign tertian parasites in his blood in mid-December 1933, when he was given a course of atabrin consisting of 0.1 gm. twice a day for five days which cleared his blood of parasites. Within a week of beginning treatment there appeared yellow discoloration of the conjunctiva and strong yellow coloration of the skin, most marked on face, palms and soles. This increased until the boy looked as if powdered with turmeric. About the same time low pyrexia ranging to 99 or 100°F. began. Urine was yellow, atabrin-positive and continued discoloured for about six weeks, but the cutaneous pigmentation and the low pyrexia persisted and the anæmia began to get worse. A thorough investigation revealed an active streptococcal infection in the throat. Intensive anti-anæmic treatment and a course of anti-streptococcal vaccine and local anti-virus applications improved the general and blood conditions and controlled the pyrexia by the middle of March 1934, but still there remained atabrin pigmentation, though in a less marked and patchy form, on the hardened skin of palms and soles and to a lesser extent on the face.

After being apparently well for a fortnight, he suddenly on the 1st of April developed a very acute illness caused by streptococcal septicæmia localizing in a patchy lobar pneumonia. Anti-streptococcal serum was given with marked effect. At the end of this severe illness which lasted for a week and which naturally left the boy more anæmic, he was observed to have lost all residual traces of atabrin discoloration. He is now making a rapid recovery in general health and blood condition.

This case suggests that the intercurrent streptococcal infection had something to do with the atabrin retention in the system. This retention was prolonged to the extent of over three months and only when the toxin was neutralized and its depots destroyed, did the tissues part with the last traces of the drug. The explanation of how this occurs is, however, not at present clear.

A CASE OF CALCINOSIS

By A. K. M. MUJIBUR RAHMAN, L.M.F., L.T.M.
D.B.M.S.

*Blair Indoor Hospital and Charitable Dispensary
Sarishabari, Mymensingh*

In September last, I saw a Hindu female about 80 years of age who had been suffering from occasional pain in her right gluteal region for twenty-two years. I considered it to be a case of rheumatism and treated her accordingly, but with no effect. On deep palpation I felt a hard substance in the muscle. On opening the part more than a dozen calculi each about the size of a pea were extracted; each was in a different cavity. The wound healed by first intention and the patient was cured.

One of the stones was sent to the Calcutta School of Tropical Medicine where it was examined and found to be a deposit of carbonates and phosphates of calcium and magnesium with traces of cholesterol and the case was accordingly diagnosed as one of calcinosis.

My thanks are due to Major S. Nag, I.M.S., Civil Surgeon, Mymensingh, for permission to publish these notes.

A CASE OF MACRODACTYLY

By K. B. SEN ROY, B.Sc., M.B., B.S., P.M.S.

Medical Officer, District Hospitals, Ghazipur, U. P.

S., a Hindu girl, aged 10 years, of the village Saraiyan, in Ghazipur district, was admitted into the hospital with abnormal enlargement of the right middle finger.

She came to the hospital for its removal, as she had been feeling its weight. It is seven and a half inches in length and seven and a half inches in diameter at its thickest part. The left middle finger is three inches in length and two inches in diameter.

The right index and ring fingers are disproportionately thicker and bent towards the thumb and the little finger respectively, as is clearly shown in the illustration. The girl uses the right thumb and the index finger to hold the handle of the grinding mill while grinding corn.

The finger was successfully amputated at the metacarpophalangeal joint by Dr. R. S. Bhargava, Civil Surgeon, Ghazipur, to whom I am indebted for permission to publish these notes from the hospital records.

CORRIGENDUM

In Lieutenant-Colonel R. N. Chopra's paper, 'Drug Addiction in India and Its Treatment', which appeared in our March issue, on p. 123, first column, fourth, fifth and sixth lines from the bottom, the words 'the incidence of addiction in British India ranges between 0.5 to 1.0 per thousand of the population' should read 'the incidence of addiction in British India ranges between 0.5 to 1.0 per cent of the population'.

Indian Medical Gazette

APRIL

ATEBRIN MUSONATE

IN this number of the *Gazette* will be found a report by Doctors Blaze and Simeons on the clinical effect of atebirin musonate in malaria in Colombo. The first results with this new atebirin compound seem to suggest very strongly that it is more powerful in its anti-plasmodial action than atebirin dihydrochloride. If the cases reported are a consecutive and unselected series, one can go further and say that they provide definite evidence that this salt of atebirin given by the parenteral route is superior to atebirin dihydrochloride administered orally, as there is no evidence to suggest that the malarial infections in Ceylon show any special amenity to treatment nor hitherto has any such striking series of results been published.

The results can be summarized shortly as follows:—

Of the 21 patients three received oral atebirin also and can be left out of consideration.

Eight patients received a single injection of 0.3 gramme of atebirin musonate intramuscularly; in two cases this completely failed to control the fever; in two it controlled the fever temporarily, but further treatment had to be given; in one it controlled the fever but parasites reappeared in the blood, so further treatment was given; and in three cases it controlled the fever completely, and no further treatment was necessary.

Nine patients received two injections on successive days (or within 36 hours, in two cases); in all the fever was controlled by this dosage, but in one parasites reappeared, so another injection was given.

Both malignant and benign tertian infections are represented in this series; the indications are that the benign tertian cases responded more readily. The cases were not of course followed up for any length of time, but whatever the final result is in these cases, the immediate result seems to have been very satisfactory.

However, we must disagree with some of the contentions of these writers. In the first place they will find their statement, that atebirin orally has no action either on the parasites or on the fever within the first three days of its administration, contradicted in practically every paper that has been published on the clinical action of atebirin. It is only necessary to cite a few papers published in this journal to refute this statement. In the first paper published on the effect of atebirin, Napier and Das Gupta (LXVII, 181) reported that the average duration of fever was less than two days after the

first administration of atebirin, and that a mean dosage of 0.525 g. was required to bring down the temperature; in this series admittedly the mean time of persistence of the parasites was more than three days, but a reduction in the numbers was always evident before the fourth day, and in some of the cases they had disappeared within the first three days. Chopra, Das Gupta and Sen (LXVIII, 425) in a slightly larger series found that in 7 out of 18 cases the parasites had disappeared by the third day, and Chopra and Sen (LXIX, 392) reported a case of very heavy malignant tertian infection in which the parasites had completely disappeared after 0.7 gramme of atebirin.

On the other hand, a number of observers have suggested that in man the action of atebirin is a little slower than that of quinine, though the statement is by no means universally accepted; now Chopra and Das Gupta (LXVIII, 493) have shown that in the plasmodium infections of monkeys atebirin is much more rapid in its action than quinine, and in these experiments the parenteral route is the one used, so that it is possible that there is some advantage to be gained in administering atebirin, whether in the form of a dihydrochloride or of a musonate, by this route. We cannot, however, accept the explanation for this given by these authors. Hecht, whom they have quoted, stated that the method he used for showing the presence of atebirin could not be used for demonstrating its absence. Further, his observations seem to suggest that by whatever route atebirin is given it is 'selected' by the liver, as are all dyes of this group, though in the case of parenteral injections it will take a more devious course before reaching this organ.

Again it is difficult to see in what way the work of Tropp and Weise supports Doctors Blaze and Simeons' contention; the excretion of atebirin in the urine commences on the first day and rises sharply reaching a maximum on the fourth or fifth day of its administration; this excretion curve does not differ in any way from that of many other drugs and certainly does not suggest a latent period whilst the liver is becoming saturated.

It seems to us far more likely that the superiority of atebirin musonate over the hydrochloride salt—if this can be established—will be attributable to differences in chemical combination, and associated differences in its dissociation, solubility or diffusibility, than to differences in the route by which it has been administered in these cases, or more probably still both the route and the chemical combination of the drug will be shown to be important factors.

Even after using it clinically for centuries, we still have no exact knowledge regarding the action of quinine on the malarial parasite; our ignorance regarding the action of atebirin is, if possible, more complete. A certain amount of work on the distribution of quinine in the body

after its administration by different routes has been done, but very little on the distribution of atebtrin; more exact methods than that devised by Hecht will have to be evolved. If further work shows that the parenteral route is more effective than the oral, or that atebtrin musonate is more effective than atebtrin dihydrochloride, not only will an advance in the treatment of malaria have been made but we shall have more data on which to work out the action of these drugs on the parasite.

However, the important matter on hand is the practical value of the observations of the two workers, and, if the results reported are taken at their face value, we must admit that an advance of very great practical importance has been made. Reports from Ceylon that we have received through a private channel indicate that the hospital experiment reported in this number has already been applied in the field. In a malaria-stricken area, in a village where practically the whole population was affected with malaria and had already suffered a heavy mortality, a single intramuscular injection was given to each of about a hundred of the villagers; the immediate effect was so marked that the rest of the inhabitants of the village demanded injections on the next day; on the third day a second injection was given to each patient, and in that village the epidemic, as an epidemic, was ended. It cannot of course be said that the malaria was ended; we know nothing about the relapse rate following this abbreviated atebtrin course, but as an emergency measure it was very effective.

The importance of an experiment of this kind must not be exaggerated; we know that quinine given by the mouth will cure malaria and that, had each one of these villagers taken a course of quinine when he or she first had fever, the results would probably have been very nearly as good; further it requires less skill to administer a tablet of quinine than to give an intramuscular injection; on the other hand it takes a much more elaborate organization to ensure that 100 illiterate villagers of all ages take three, or even two, tablets of quinine a day over a period of seven days, than to give them two injections of atebtrin musonate at an interval of 24 hours.

However, considering the matter dispassionately, these first reports do seem to indicate that another advance in malaria therapy has been made.

The two main complaints made against atebtrin have been its reputed slower action than quinine and its higher price; atebtrin musonate meets the first complaint completely, and the economic difficulty of using it on an extensive scale, in an epidemic for example, should be largely overcome, if two doses will control a malarial attack. We shall await further reports with considerable interest.

CALCUTTA MEDICAL COLLEGE 1835—1935

At the beginning of the last century medical education, as it was conducted in Great Britain and in many countries in Europe at that time, was non-existent in Bengal or in any other province of India. Before the advent of the British, the people of India had depended for medical attention on the *vaids* and *hakims*, the practitioners of the indigenous systems. These systems had undoubtedly at one time been far ahead of their European contemporaries, but through the centuries they had degenerated, as all dogma-bound systems must degenerate, and were mainly represented at that time by poorly educated and often illiterate quacks.

For the treatment of the servants of the East India Company and for the Army in India doctors from Europe had to be imported. These men naturally trained assistants in their hospitals, but there was no systematic course for these assistants to go through and they acquired no status. This was an unsatisfactory state of affairs which led through natural stages to the establishment, first, of a small medical school. It was probably not the failure but rather the success of this medical school, which had demonstrated the potentialities of such a scheme, that led to its abolition after a career of about a dozen years and to the establishment in the year 1835 of the present medical college, where a systematic medical training strictly in accordance with the methods adopted in Europe was given.

The government order establishing this college provides interesting comparisons with the state of affairs at the present day. The work of instruction was to be carried out by the superintendent and one assistant. After instructing fifty students in anatomy, surgery, medicine and pharmacy, issuing half-yearly reports, and conducting examinations, the superintendent would, we should imagine, have little time, or inclination, to indulge in private practice, but nevertheless there was an explicit clause forbidding him to do so. This wise principle was abandoned in later years and has only recently been applied again. For clinical instruction five local medical institutions were named. However, soon after its establishment the college organized its own 'clinics', though it was not until 1852 that a hospital of any size was built; in that year, the main building of the hospital as it stands to-day was opened by Her Majesty's Governor-General in India, the Earl of Dalhousie.

In the year 1857 the Calcutta University was founded and the college was affiliated to it in the same year.

The principle of giving training strictly in accordance with the system adopted in Europe has been followed throughout the years and the

medical college has seldom lagged far behind the medical colleges of Great Britain in its adoption of new methods, either of treatment or of instruction. From its modest beginnings with a superintendent and one professor, it now has a principal and seventeen professors, the students have increased from 50 to 655, and in the medical college compound there are half a dozen buildings each almost as large as the original block. When the new casualty ward is built the total number of beds available will be 738 and we imagine that the ground space of the compound will have reached saturation point; subsequent extensions, and we hope there will be many, will have to be upwards.

The college has had many distinguished professors who have left their mark on medicine

in general, and on tropical medicine in particular, and an even larger number of distinguished students who have carried its fame throughout India and across the seas to other lands. The present staff and students of the college have behind them a great tradition and therefore a great responsibility. The changes of the staff during the last few years have been very considerable, and the vast majority of the professorships are now occupied by 'non-service' men; even if these men have not the tradition of the 'service' behind them they have the tradition of the college, and we have every reason to hope that they will shoulder this responsibility, as their 'service' confrères have done in the past, and both maintain and add to the fame of the Calcutta Medical College.

Special Article

TONSILLECTOMY BY A COMBINATION OF DISSECTION AND GUILLOTINE OPERATION

By SUKH DAYAL, M.B., B.S. (Ald.), D.L.O. (Lond.)
D.O.M.S. (Lond.), F.R.F.P. & S. (Glas.), F.R.C.S. (Edin.)
Lecturer of Surgery and Diseases of the Ear, Nose
and Throat, Medical School, Agra

ONE of the main considerations in the removal of tonsils is the control of hæmorrhage and the plea for writing the present article is to indicate a method which reduces the hæmorrhage to a minimum and at the same time effectively removes the diseased tonsils. Many a patient's guardians are afraid of the bleeding and it is no less embarrassing to the operator when it occurs to any marked extent. An ideal operation should aim at complete removal of the tonsils with the capsule intact, without injury to the fauces or the soft palate. Complete removal except in the case of the deeply buried tonsils can be effectively carried out with an ordinary guillotine, but one often comes across cases in which the pillars of the fauces or the uvula have been injured, and in the case of the deeply buried tonsils the instrument is often ineffective and sufficient portions of the diseased tonsils are left behind which overgrow in no time and keep up the focus of infection for the removal of which the operation was mainly undertaken. To obviate this difficulty one has to resort to dissection but this entails considerable bleeding. To meet these difficulties the following combined method has been adopted for the last year at the Thomason Hospital, Agra, and it has given uniformly good results without a single mishap in the numerous operations undertaken during the period. The method outlined below is applicable in the removal both under local and general anæsthesia, the former being the method of choice

in the case of adults, and the latter in the case of children and females and in adults with fibroid tonsils.

Preparation.—Any septic foci in the mouth, as for example carious teeth and alveolar abscesses, are at first suitably dealt with. The patient is given an antiseptic alkaline mouth wash for a couple of days, and to guard against hæmorrhage calcium lactate, grains x, is given thrice a day for a couple of days before the operation. In cases which are going to be done under general anæsthesia, a dose of castor oil is administered on the eve of the operation and a soap-water enema the next morning.

Operation under general anæsthesia.—There are a number of different patterns of guillotines, but the one that has given uniformly good results in the writer's hands is the Clayton's instrument. It has got the advantage of having detachable blades with rings of different sizes, and by a spring and screw action it clamps the pedicle and gradually crushes and cuts through it, and completely arrests the hæmorrhage. The other special instruments required are a Davis' mouth gag, a Mayer's tonsil enucleator, a pair of instruments with serrated edges and a point, a vulsellum, about four sponge-holders, a Shipway's anæsthesia apparatus and, as most of the tonsil cases have adenoids also, it is an advantage to keep a La Forge's adenotome also at hand. The Davis' mouth gag has the advantage that, while keeping the mouth open, it keeps the tongue depressed and provides anæsthesia through a tube attached to the tongue depressor and keeps the anæsthetist out of the way. The Shipway's apparatus has the advantage that, as soon as the anæsthesia has been induced with chloroform, ether or a mixture of ether and chloroform can be turned on. If a forehead light or a lamp with condensor and a forehead mirror are available, besides the

anæsthetist, one does not require more than one assistant.

The anæsthetist and the assistant should know their jobs well. The assistant should be very quick in handing over instruments and swabs which are made out of cotton-wool soaked in an antiseptic lotion, such as 1 in 100 carbolic, and squeezed dry. If a forehead light or a suitable lamp and a forehead mirror are not available, one more assistant is required to throw light into the patient's mouth with an ordinary electric hand torch. The patient having been placed in the dorsal position, a sand bag is placed under the shoulders so as to hang the head low and prevent any blood being inhaled. Two sterilized towels are slipped under the head, one of these being spread under the head and the other wrapped round it and the body is covered with a sterilized sheet.

The anæsthesia is induced with ehloroform with the ordinary mask of the inhaler and, as soon as the patient is under, the face is swabbed with ether, and the Davis' mouth gag inserted. The throat is cleaned of any saliva that may have collected in the meantime, and the surgeon takes his position on the right side of the patient, the chief assistant with the instruments standing to the right of the operator and the anæsthetist on the left side of the patient's head. The mouth gag is dilated and a careful watch kept on the patient's respiration, because it often happens that as soon as the patient's mouth is fully dilated the patient holds his breath. If this happens, the mouth gag is relaxed and breathing is quickly re-established.

Under good illumination the tonsil is caught with the vulsellum, pulled towards the middle line, the point of the dissector is passed under the anterior pillar of the fauces and the latter is lifted up from the tonsil. The serrated edge of the enucleator helps in separating the pillars from the tonsil and its attachments above and below without injuring the uvula. This separation is carried on till a narrow pedicle is left. In the meantime a careful watch is kept on the patient's breathing and colour of the oozing blood; if the latter appears to be dark it means insufficient breathing and the mouth gag is at once relaxed when the breathing restarts freely. If there is any cyanosis as indicated by the dark colour of the blood, oxygen should at once be connected from a cylinder, which should be always kept at hand, to the Shipway's inhaler. This quickly improves the colour of the patient and obviates any danger of asphyxia. At the same time the throat should be thoroughly swabbed out.

As soon as the tonsil is sufficiently free, the vulsellum is removed and slipped through the ring of the Clayton's guillotine and the tonsil is caught with it and pulled towards the middle

line. The vulsellum after application is handed over to the assistant who keeps the tonsil suitably pulled towards the middle line and the ring of the guillotine is slipped over the tonsil on to the pedicle and its distal edge passed well behind the tonsil. The guillotine is manipulated with the right hand in such a way that, while the distal edge of the ring is well behind the tonsil, the proximal edge of the ring should lie between the anterior pillar of the fauces and the tonsil. This becomes easy if the operator with his left index finger exerts a little pressure over the anterior pillar slightly behind the edge, thereby effectively pushing the tonsil through the ring of the guillotine.

The uvula is inspected to make sure that it does not lie in the ring of the guillotine and this is rarely the case if the proper size of blade is selected. Having ascertained these points, the operator pushes his thumb into the proximal ring of the guillotine and presses it gently down. Any pressure with the left finger over the anterior pillar of the fauces is removed to avoid button-holing the latter. The proximal ring of the guillotine is then pressed in as far as it will go and this constricts the blood vessels in the pedicle. The thumb ring is then gradually turned thereby crushing the pedicle and cutting through it; the tonsil then comes away with the vulsellum.

A swab on a sponge-holder is then pushed into the bed of the enucleated tonsil and kept pressing laterally from three to five minutes and an iced towel is placed under the jaw. This almost completely stops the bleeding and, if any still persists, the ordinary swab is replaced with one soaked in hydrogen peroxide thoroughly squeezed.

While the hydrogen-peroxide swab is being applied another ordinary swab on a sponge-holder should be kept ready at hand to remove quickly the froth produced with hydrogen peroxide and to save the patient from being choked.

Having stopped all oozing the operator goes over to the left side of the patient, the assistant remaining on the right and enucleation of the right tonsil is begun in the same way.

Any adenoids present are then removed with the La Force's adenotome which is passed behind the soft palate and kept gently pressed against the posterior wall of the pharynx keeping the instrument in the middle line. With the thumb, the ring of the blade is pulled out and any adenoid tissue pushed into the box of the adenotome is shaved off by pushing the blade home with the thumb. This instrument has the advantage over the ordinary Gottstein's curette in that there is no tearing and stripping down of the mucous membrane of the posterior pharyngeal wall and so no tags are left behind which are often the source of bleeding. The removal of adenoids is followed by smart bleeding, which wells up through the

nose. To stop this bleeding a fairly big sponge is pushed well behind the soft palate and pressed against the posterior pharyngeal wall. At the same time cold water is poured on the patient's head and the face is splashed with a cold towel and this stops the bleeding very quickly.

Removal under local anaesthesia.—This can be done without any assistant if a good forehead light or a suitable lamp and a forehead mirror are available. After painting the throat with 5 per cent cocaine 1 to 2 per cent solution of novocaine is injected into the bed of the tonsil and into its upper and lower pole with a Dan Mackenzie's tonsil syringe. The addition of a little adrenalin chloride solution effectively controls the hæmorrhage, but it has the disadvantage that it sometimes gives rise to reactionary bleeding, though this is rarely profuse. The operation is done with the patient seated in a chair opposite the operator, the steps of the operation being the same as under general anaesthesia.

Post-operative treatment.—The patient is kept lying on the side with a kidney tray close by to receive any vomit, and a few sponges on sponge-holders to swab out the mouth. A cold towel is kept round the neck for some time and when the patient comes round he is given bits of ice to suck. The throat is frequently sprayed out with pure hydrogen peroxide and in between the sprays the patient gargles with an antiseptic alkaline lotion.

Calcium-lactate powders are continued for the next forty-eight hours. The patient is not given any feed till the evening, only ice and lemonade being allowed. Later on barley water, tea or soup may be allowed, milk being unsuitable, as it sticks in the throat which becomes

difficult to clean. After every feed the mouth is sprayed and gargled. If the pain is severe as often happens towards the end of the day, a powder containing aspirin and caffeine is administered and fomentations applied to the neck or a powder containing equal parts of orthoform and anæsthesine is blown over the fauces. No solid food is allowed for the first three days, after which semi-solid food is commenced, gradually going on to the solid diet. On the day following the operation the fauces are seen covered with a white slough which gradually disappears under hydrogen-peroxide sprays and antiseptic gargles, taking about a week to disappear completely.

Under the technique described above there is rarely any troublesome hæmorrhage, but if any occurs it should be completely arrested before the patient leaves the operation table. Some of the methods to arrest the bleeding have been already described above; any smart bleeding should be controlled by the application of an artery forceps—Schumacher's type being particularly useful—and a ligature. For any general oozing the tonsil bed should be packed with a strip of gauze soaked in hydrogen peroxide and, if this is also ineffective, a roll of gauze is packed in the tonsil bed and the pillars stitched over it with a couple of stitches. Some special instruments, *e.g.*, Watson William's hæmostat, have been devised for the purpose, but where the ordinary means to arrest the hæmorrhage fail, which has never been known to occur under the technique described above, these instruments are rarely of any use, and actual ligature of the bleeding point, or stitching of the pillars over a piece of gauze, has to be resorted to.

Medical News

CALCUTTA MEDICAL COLLEGE CENTENARY

DURING the early part of February the Medical College, Bengal, celebrated its centenary. On 4th February in the presence of a large gathering of present and past students and professors, and of a large number of visitors, the Honourable Sir Bijoy Prosad Singh Roy, Kt., M.A., B.L., Minister in charge, Local Self Government Department, Government of Bengal, the President of the Executive Committee of the Medical College Centenary, opened the proceedings, and His Excellency the Right Honourable Sir John Anderson, P.C., G.C.B., G.C.L.E., Governor of Bengal, laid the foundation stone of the new Casualty Ward which is to be built to celebrate the occasion. The money for this new ward has been raised by public subscription. Up to the present a sum of 3 lakhs has been collected, but for the full scheme that is contemplated a sum of 5 lakhs will be required.

A series of scientific lectures had been arranged and these were delivered during the week in the main lecture theatre of the college. A scientific exhibition had been organized in the various departments of the college and in the associated hospitals and institutions, and in a series of temporary booths in the

grounds; the exhibition of pathological specimens was of special interest.

A very large number of old students now working in other places in Bengal and in more distant parts of India took this opportunity to visit Calcutta and attend the various social and scientific functions. The whole proceedings were a great success and worthy of the unique occasion, the celebration of the centenary of India's most famous medical college. Much credit is due to the organizers and especially to the secretaries of the various committees, Lieutenant-Colonel T. C. Boyd, I.M.S., the Principal of the College, Dr. M. N. De, and Dr. A. C. Ukil, on whom, we have little doubt, a very large bulk of the hard work devolved.

POST-GRADUATE INDIAN STUDENTS AT THE NEW MEDICAL CENTRE IN LONDON

TWENTY-ONE post-graduate Indian medical students visited the medical section of British Industries House, London, during January this year.

They attended under the leadership of Mr. J. S. Aiman, Warden of the Indian Students' Union Hostel

attached to University College, and although only fifteen originally signified their intention to be present, six others cancelled their afternoon's lectures, so as not to miss an opportunity of inspecting the only composite exhibition of its kind in the world.

As future medical practitioners, hospital officials, and members of the Indian Medical Service, the visitors showed keen interest in everything they saw—and that was a great deal.

This section of British Industries House carries out in the sphere of pharmacy and surgery the general principles which mark the House as the greatest advance in Empire Trade development yet evolved. Exhibitors include manufacturers of the latest appliances and equipment in use throughout the profession.

It was not as a permanent exhibition that the section attracted the visitors' interest, but as a buying centre where all their needs can be satisfied under one roof.

The saving of time to hospital executives in thus being able to inspect and choose their requirements from a single hypodermic needle to a complete ward or operating theatre, all gathered together compactly and displayed under actual service conditions, is inestimable. The recent equipment of an extension to Barnsley Hospital at British Industries House is a case in point, and the Barnsley authorities calculate that, travelling only from Yorkshire, their reduced time and expenses were very considerable.

The great saving in time and trouble, not to mention assurance of up-to-date-ness in everything bought, to Indian doctors and hospitals that the establishment of this centre effects, was the aspect which appealed to to-day's visitors, whose spokesman said that nowhere in Europe or the world at large are similar advantages obtainable.

The medical centre occupies approximately twenty thousand feet of space in the building and functions under a strong advisory council composed of members of the staffs of the leading London hospitals.

The area is divided into two sections, one comprising a permanent display of hospital equipment, medical and surgical requisites, dressings, pharmaceutical preparations, hospital fittings and so forth, and the other a model hospital suite including two completely furnished operating theatres, a twelve-bed ward and solarium. This suite is presented as an example of modern hospital layout and equipment.

THE TENTH INTERNATIONAL CONGRESS OF THE HISTORY OF MEDICINE

THE Tenth International Congress of the History of Medicine will take place in Madrid, Spain, from the 23rd to 29th September, 1935. English will be one of the official languages of the Congress. The Congress fee is 100 pesetas.

Medical men desirous of attending the Congress should write to the Señor Secretario Del X Congreso Internacional De Historia De La Medicina, Palacio de la Academia Nacional de Medicina, Calle de Arrieta, 12, Madrid (Spain).

Papers for the Congress should be submitted in time to be received by 1st June, 1935.

BENGAL MEDICAL ACT

THE following extract from a Government notification regarding a draft of amendments, which, in exercise of the power conferred by sub-section (1) of section 33 and clauses (b), (c) and (d) of sub-section (2) of section 33 of the Bengal Medical Act, 1914 (Bengal Act VI of 1914), the Governor in Council proposes to make in replacement of the rules and forms previously published, is published for the information of persons likely to be affected thereby.

The draft will be taken into consideration on or after the 15th of April 1935, and any objection or

suggestion received by the secretary before that date will be duly considered:—

Draft amendments

Rules under clause (d) (i) of sub-section (2) of section 33 of the Act.

Procedure to be followed in conducting any enquiry referred to in proviso (b) to section 17 and clause (a) of section 25 of the Act.

Whenever information is received that a medical practitioner, who is an applicant for registration, or whose name has already been registered, has been guilty of conduct which *prima facie* constitutes infamous conduct in a professional respect, the Registrar shall make an abstract of such information and of such further information he may have subsequently obtained.

Where the information in question is in the nature of a complaint by a person or body charging the practitioner with infamous conduct in a professional respect, such complaint shall be made in writing addressed to the Registrar, and shall state the grounds of complaint and shall be accompanied by one or more declarations as to the facts of the case except when the complaint is by a government department.

Every declaration must state the description and true place of abode of the declarant, and where the fact stated in a declaration is not within the personal knowledge of the declarant, the source of the information and grounds for the belief of the declarant in its truth must be accurately and fully stated.

(1) The abstract and all other documents bearing on the case together with any complaint that may have been lodged shall be submitted by the Registrar to the President, who shall, if he thinks fit, instruct the Registrar to ask the practitioner by means of a registered letter for an explanation within a time to be fixed by the President. After the expiry of that time the documents with the explanation, if any, shall be referred for consideration to a Penal Cases Committee which shall be appointed by the Council. The Committee shall have power to cause further investigation to be made and further evidence to be taken and, if necessary, obtain further legal or other advice.

The Committee shall report to the Council, and if the Council consider that the case is one in which an enquiry ought to be held by the Council, the President shall direct the Registrar to take steps for the institution of an enquiry and for having the case heard and determined by the Council.

The enquiry shall be instituted by the issue of a notice in writing, on behalf of the Council, by the Registrar, addressed to the practitioner. Such notice shall specify the nature and particulars of the charge, shall inform the practitioner of the day on which the Council intend to deal with the case, and shall call upon him to answer the charge in writing and to attend before the Council on that day.

The notice referred to in rule 9 shall be sent at least twenty-one days before the date of the enquiry, and shall be accompanied by a copy of section 17 or 25 of the Act, as the case may be, and of the rules to regulate the procedure for conducting any enquiry referred to in those sections. A copy of the notice should at the same time be sent to the complainant, if any.

In every case in which the Council resolve that an enquiry shall be instituted and a notice for an enquiry is issued accordingly, the complainant (if any) and the medical practitioner charged shall, upon request in writing for that purpose signed by him or his legal representative, be entitled to be supplied by the Registrar with a copy of any declaration, explanation, answer or other document given or sent to the Council by or on behalf of the other party, which such other party will be entitled on proper proof to use at the hearing as evidence in support of or in answer to the charge specified in the notice of enquiry.

Any application made by the medical practitioner between the date of issue of the notice and the day named for the hearing of the charge shall be dealt with by the President in such manner as he shall think fit.

All material documents which are to be laid before the Council as evidence in regard to the case shall be printed, and a copy shall be furnished to each member of the Council before the hearing of the case.

At the hearing of the case by the Council, the complainant and also the practitioner may be represented or assisted by a legal representative.

Where a complainant appears personally or by a legal representative, the order of procedure shall be as follows :—

- (1) The Registrar will read to the Council the notice of the enquiry addressed to the practitioner.
- (2) The complainant will then be invited to state his case himself or by his legal representative and to produce his proofs in support of it. At the conclusion of the complainant's proofs his case will be closed.
- (3) The practitioner will then be invited to state his case himself or by his legal representative, and to produce his proofs in support of it. He may address the Council either before or at the conclusion of his proofs, but only once.
- (4) At the conclusion of the practitioner's case, the Council will, if the practitioner has produced evidence, hear the complainant in reply on the case generally, but will hear no further evidence except in any special case in which the Council may think it right to receive such further evidence. If the practitioner produces no evidence, the complainant will not be heard in reply, except by special leave of the Council.
- (5) Where a witness is produced by any party before the Council, he will be first examined by the party producing him, and then cross-examined by the adverse party, and then re-examined by the party producing him. The Council may decline to admit in evidence any declaration where the declarant is not present for, or declines to submit to, cross-examination.
- (6) The chairman of the meeting may put questions to any witness, and members of the Council, through the chairman, may also put questions to any witness.

Where there is no complainant, or no complainant appears, the order of procedure shall be as follows :—

- (1) The Registrar will read to the Council the notice of enquiry addressed to the practitioner and will state the facts of the case and produce before the Council the evidence by which it is supported.
- (2) The practitioner will then be invited to state his case himself or by his legal representative, and to produce his proofs in support of it. He may address the Council either before or at the conclusion of his proofs, but only once.

(1) Upon the conclusion of the case the Council will deliberate thereon in private, and at the conclusion of the deliberations the chairman shall call upon the Council to vote on the question whether the medical practitioner charged is guilty of infamous conduct in a professional respect.

(2) If the Council, by a majority of two-thirds of the members present and voting at the meeting, find the medical practitioner guilty of infamous conduct in a professional respect, the Council shall direct the Registrar not to register his name, if he be an applicant for registration, or to remove his name from the register of registered practitioners, if he is already a registered practitioner or to warn or to censure him.

When the registration of the name of any practitioner is refused, or when the name of any registered practitioner is removed from the register in accordance

with the provisions of the preceding rules, the Registrar shall forthwith send notice of such refusal or removal to the practitioner, by a registered letter addressed to his last known address. The Registrar shall also send, forthwith, intimation of any such refusal or removal to the body or bodies from whom the practitioner received his qualification or qualifications, and shall request them not to admit him without previous reference to the Council to any examination for any new qualification, which is registrable in the register of registered practitioners. If a name is removed from the register, the Registrar shall issue a notification in the *Calcutta Gazette* announcing the removal and forward a summary of the proceedings and findings to the medical journals for publication.

INDIAN MEDICAL COUNCIL

COLONEL H. C. BUCKLEY, Inspector-General of Civil Hospitals, Bihar and Orissa, has been duly nominated by the Government of Bihar and Orissa under clause (a) of sub-section (1) of section 3 of the Indian Medical Act, 1933 (XXVII of 1933), as a member of the Medical Council of India vice Lieutenant-Colonel P. S. Mills, I.M.S., resigned.

THE PUNJAB MEDICAL COUNCIL

JUDGMENT has been delivered by a first class magistrate, Ambala city, in a case under section 23 of the Punjab Medical Registration Act II of 1916, under which one Pars Ram, an unqualified medical practitioner, described himself as a registered medical practitioner. The accused has been convicted and sentenced to pay a fine of Rs. 100 on a complaint lodged by the Punjab Medical Council.

THE ALL-INDIA OPHTHALMOLOGICAL SOCIETY

IN continuation of the previous notice, the fourth conference of the All-India Ophthalmological Society will be held in Madras, from the 22nd to the 24th April, 1935, under the presidency of Lieutenant-Colonel R. E. Wright, I.M.S. One session will be devoted to a discussion on Nutritional Disorders of the Eye in which Lieutenant-Colonel Sir J. N. Duggan, Dr. S. K. Mukerjee, Lieutenant-Colonel E. O'G. Kirwan, Dr. B. K. Narayana Rao and others will take part.

All ophthalmic surgeons who are not already members of the Society are requested to join and help to make the conference a great success. The Society has over 110 members on its rolls. The subscription has been reduced to Rs. 10. Application for membership may be made to Dr. G. Zachariah, 'Flitcham', Marshall's Road, Egmore, Madras, or Dr. B. N. Bhaduri, 10-5-A, Wellington Street, Calcutta.

THE NATIONAL BIRTH CONTROL ASSOCIATION

THE National Birth Control Association has appointed a medical sub-committee consisting of practitioners actively engaged in the teaching of contraception. The object of this committee is to collect, co-ordinate and from time to time draw up for publication by the N. B. C. A. authoritative information on all aspects of contraception, for the use of the medical profession.

This committee is in consultation with research workers, manufacturers, birth control clinics (both voluntary and under the public health authorities) and doctors engaged in teaching contraceptive methods throughout the country.

Although much valuable experience exists, the results of which are at the disposal of the N. B. C. A., the whole subject is still at the research and experimental stage, and it is necessary to be constantly reviewing and re-assessing the methods in current use.

This committee would therefore be glad to hear from any doctor, clinic or manufacturer interested in birth control, in order that it may have the fullest sources of information possible.

All communications should be addressed to the Secretary, the National Birth Control Association, 26, Eccleston Street, London, S.W. 1.

MARRIAGE HYGIENE

We have now received two copies of a new quarterly publication, *Marriage Hygiene*.

The journal proposes to deal with subjects connected with eugenics, race welfare, social hygiene, contraception and marital adjustment.

The first numbers represent an international aspect of this subject and the contributors include such well-known writers as Marie Stopes, Havelock Ellis, C. P. Blacker, and scientists such as Julian Huxley and Cecil Vogt. The Indian point of view is well represented by Lieutenant-Colonel S. S. Sokhey and R. C. Rakshit.

There are articles on contraception, but the aims of the journal are much higher than the provision of 'sex literature' in its popular and worst sense. A few of the titles are 'Medical education in relation to sex', 'Indian outlook in sex relations', 'The problem of sterilization' and 'Eugenics in relation to health and disease'.

Each number contains abstracts of suitable articles taken from the medical journals of many countries, and also reviews.

The journal is edited by Dr. A. P. Pillay and is printed in Bombay. It compares very well in appearance with high-class quarterly journals published in Europe and America, and appears to be entirely free from the blemish of misprints that are so liable to disfigure medical publications in this country.

We congratulate the editor wholeheartedly on the high standard he has achieved in the first two numbers, and we wish the journal every success.

THE BRITISH JOURNAL OF TUBERCULOSIS

We have just received the first number of volume XXIX of this journal. Since the last number was issued there has been a change in both its editorship and its format. The present format is certainly a very satisfactory one, and, though we had never felt that there was very much room for improvement, we now see that a considerable improvement has in fact been effected. In the matter of clarity of type, quality of paper, and general layout the journal now compares favourably with any specialist medical journal published in England or America.

With the change of editorship there are to be certain changes in the policy of the journal; it is naturally difficult to pass any judgment on these from the perusal of a single number, but from the editorial note we gather that the object is to make the journal more practically useful to the general medical reader, by the inclusion in each number of clinical articles. This is an excellent principle, as specialist journals are liable to be devoted to the reports of abstruse investigations of specialist research workers, which investigations may be important, but often have no obvious practical application, and are only appreciated by the very few.

The present number contains a useful practical article by professor Lyle Cummins on the problem of acute pulmonary tuberculosis in young females, one on the tuberculin treatment of phthisis, a radiological paper on Assmann's focus, and several other valuable contributions. There is a short report of a clinical case—death following artificial pneumothorax refill—and a 'consultation'; both these are to be constant

features of the journal in future. The rest of the number is devoted to meetings of societies, abstracts, and reviews of books.

We hope that this journal will have a wide circulation in this country. Tuberculosis in India admittedly has special features of its own, but it is sometimes forgotten that it has far more features in common with tuberculosis in other countries than special ones.

The new editor is Dr. L. S. T. Burrell, M.A., M.D., M.R.C.P.

JOURNAL OF THE RAJSHAHI DISTRICT BOARD MEDICAL ASSOCIATION

This association has decided to publish its own journal. The editor details the circumstances that have lead to this decision, and expresses the ideals of this new venture in the first number of this journal, which we have just received, thus:—

'No organized effort has ever been made to improve the scientific and professional knowledge of the medical officers and compounders of the district boards in Bengal. To the medical officers and compounders of the province have been entrusted the health of rural Bengal and these medical officers represent the strongest section of the Licentiate now organized by their separate associations. While efforts have been made towards the improvement of the status of the whole body of the Licentiate these efforts have hardly been directed specially towards improving the lot of the poor medical officers of the district boards in Bengal and actually no effort has been made for the compounders of the district boards. These officers really serve the masses and carry the banner of the humanitarian services of the board in the interior of the province under most difficult circumstances, and in every case a district board is popular or unpopular according to the services rendered by its medical department. Yet these officers have to remain satisfied with a meagre provision. They are cut off from the outside world of moving and progressive civilization; they have to remain content without the amenities of town life. Their secluded life in the villages begets in them a natural indifference rendering their lot what it is to-day now. Toiling hard the whole day long, busy with their daily routine work, they have little time to think of other things of life, even of how to improve their destitute condition.

We require to strive hard to change the inferiority complex that has taken root in them. We require also to discuss in our humble way the modern advancement of medical science; we should create an atmosphere of thinking high while we live plain.

We are aware that there are a number of scientific journals of high standard in the country. We hold out no apology to compete with these organs.

We require our own organ which by continuous efforts in future will be able to help our members to become more useful to the people they serve in every way possible. We require also a means to ventilate our grievances, to give expression of our feelings through its columns and we require to hold high up to our members that personal considerations should always be sacrificed everywhere at the bugle call of duty and in the services of humanity—so that we can keep the banner of our noble profession high aloft even in times of the greatest adversity'.

The district board medical officers are often considered to be the cinderellas of the medical profession in India, but we think that the use of expressions such as 'destitute condition' is perhaps drawing a little too gloomy a picture of their lot. However, if by means of their journal they are able to improve their position in any way, we certainly wish it a long and prosperous life. We congratulate this association on their enterprise.

THE DARBHANGA RESEARCH SCHOLARSHIP, 1935

THE following is an abridgement of a notice, dated 30th January, received by us on 13th March under a covering letter dated 13th February, from B. B. Dutt, Officiating Controller of Examinations, Calcutta University, Senate House, Calcutta, from whom further details can be ascertained and to whom applications should be made :—

Applications are invited from candidates for the 'Darbhanga Research Scholarship' for the year 1935.

The scholarship will be awarded for the purpose of encouraging original research in medicine in its various branches, and all graduates and licentiates in medicine of the Calcutta University are eligible to compete for the same. The value of the scholarship is Rs. 50 a month tenable for one year only from July 1935 to June 1936.

The scholar will be required to devote at least four hours a day, Sundays and holidays excepted, during the tenure of his scholarship to research work in any special branch of medical science to be previously selected by him and approved by the Board of Studies in Medicine.

The applications from intending candidates must reach the office of the Controller of Examinations not later than the 30th April, 1935.

Current Topics

Collosol Iodine in the Treatment of the Pneumonias

By R. V. MURPHY

(From the *Irish Journal of Medical Science*, October 1934, Sixth Series, No. 106, p. 563)

THIS treatment was introduced in a preliminary note in the *Irish Journal of Medical Science* (July 1929). Thirty cases, of which three were fatal, were then briefly described. It was shown how beginning with the 0.2 per cent solution of collosol iodine I had the 0.4 per cent and later the 0.8 per cent solutions prepared. I gradually worked my way up to the last, which is now the only one I employ. In the present series sixty further cases, of which six were fatal, will be considered. There is a total therefore of ninety cases treated, with nine fatalities. Though the number is small the preponderance of successes during a period of two and a half years, endorsed as it is to a great extent by the experience of my colleagues, justifies, I believe, some broad conclusions which will be suggested in the course of this article.

I do not intend to enter into the question of the general treatment or nursing of pneumonia. In what follows it must be clearly understood that I confine myself solely to the consideration of the intravenous treatment.

We are told that the total amount of iodine in the blood is not more than 2 mg. of which only a portion is active. Ten cubic centimetres of C.I.N.S. (collosol iodine new solution 0.8 per cent) contain 80 mg. of iodine. It would appear, therefore, that the iodine delivered in this form directly into the blood stream replenishes a failing reserve and is immediately available. Certainly in actual practice collosol iodine has proved itself to be a detoxifying agent of great range and potency—presumably where a shortage of iodine is responsible or mainly responsible for the breakdown of the mechanism of immunity. In the strength and dosage here employed the preparation is apparently free from danger of any kind.

I have been asked the questions :

(1) How often and for how long should the injections be given ? and

(2) Are there any contra-indications ?

With regard to the first question there is only one danger, so far as I am aware—that of giving up the

treatment too soon. Every case of pneumonia or of suspected pneumonia admitted under my care is given a dose of C. I. N. S. (10 e.c.m.) immediately on admission. Several thousands of injections have been given by me or under my personal supervision for a variety of conditions as well as the pneumonias and I have never met a single contra-indication. The only reaction of any kind which I have seen was a local sclerosis on a few rare occasions, and the treatment was then carried on in another vein. Sclerosis is not a contra-indication for the continuance of the treatment and does not usually recur in the site of the new puncture. I have found the treatment very satisfactory in phlebitic and thrombo-embolic conditions: periphlebitis, thrombophlebitis and phlegmasia alba dolens. Results were not less remarkable than those obtained in the pneumonias.

The cases of pneumonia and broncho-pneumonia so far encountered include every clinical variety: primary, secondary and post-operative, simple and complicated, and embrace also every bacteriological group, pneumococcus types I, II, III and IV, as well as streptococcus and Friedländer's pneumobacillus.

The treatment is still young and apart from individual factors which may modify the response in individual cases there may be external influences, epidemical, geographical and racial, the effects of which practical experience alone can decide. I shall here deal only with the former.

Most of the cases under the treatment reached the stage of crisis within three days or less, others reacted slowly, but even when recovery was delayed to a late and protracted lysis, as a rule an early mitigation of the toxæmia was a definite and welcome phenomenon. Many of the cases found in hospital, coming as they often do on the third or fourth day of the disease, or even later, from unhygienic and otherwise unsuitable environment, often arrive so ill that their removal to hospital has been an added risk. In most of these, precedent lack of health has rendered them unsuitable to face the demands made on their powers of resistance and endurance by such a severe and critical illness as pneumonia.

The straight case of uncomplicated pneumonia in which the defensive mechanism has not been overwhelmed is expected to yield to treatment in about 24 to 48 hours. A slow or poor response in what appears to be an uncomplicated case which is putting up a good fight should, I think, be taken as evidence of the presence of some hidden tuberculous or other infection which has flared into activity.

Uncomplicated post-operative pneumonia appears to be very amenable; this is easy to understand when it is remembered that the patient has been specially prepared for treatment, already in bed and under general management, on a very light diet, with the bowels well opened; the setting is ideal for the treatment, which is administered early. In the emergency operation all these details may be altered with a consequent modification of response.

Cases in private practice respond more rapidly than most hospital cases and those coming under the treatment early generally do much better than those who come under it late.

Recurrence as a rule responds very well. In the present series three patients developed recurrence whilst actually undergoing the treatment; one ended fatally. In the other two, crisis of the recurrence was completed within 24 hours.

Sputum examination was possible in only 21 cases. Of these 14 were found to belong to one or other of the pneumococcal groups. Much further investigation will be required before the exact position in this respect will be known. Of the cases in which complete examination of the sputum was possible :

- | | | |
|---|-------------------|--------------------------|
| 2 | were pneumococcus | type I. |
| 2 | " | type II. |
| 3 | " | type III (1 fatal case). |
| 7 | " | type IV. |

In 3 cases Friedländer's pneumobacillus,
 „ 3 cases streptococcus, and
 „ 1 case pneumococcus type I and tubercle bacillus
 were the predominating organisms.

I use collosol iodine frequently as a prophylactic agent. In the four cases described I think it may be inferred that other complications as well as pneumonia were successfully warded off.

In the influenza epidemic of the early months of the year 1933, I used the preparation largely in the early stages of the disease to prevent complications and sequelae, as I had found it was as suitable for influenzal pneumonia as for primary pneumonia. It did not appear to have any beneficial effect on the influenza itself, which was, therefore, treated by other means.

In consequence of the results of the treatment of thrombophlebitis and phlegmasia alba dolens I have been tempted to use the preparation with the aim of preventing post-operative thrombus and embolus. For some time I have held the view that where sepsis is not evident a dormant or quiescent pre-operative distant sepsis, awakened into occult activity in a pre-disposed subject, may frequently prove one of the predominant causative factors in this condition, and owing partly to the poor reaction of the patient and partly to the low-grade virulence of the infection known signs of infection do not present themselves and in consequence the disease develops undetected. It is possible that the thrombosis is immediately of toxic origin arising from sepsis, even though the field of operation and its neighbourhood may be all that the surgeon may desire, and it is now my rule to administer C. I. N. S. to the debilitated subject with low blood pressure and sluggish circulation before and for a long time after operation unless the integrity of the teeth, maxillary antra, respiratory tract, gall bladder, etc., has been proved to be above suspicion. While this view is awaiting final confirmation or disproof I console myself with the reflection that there does not appear to be any alternative treatment, until a vessel has actually become blocked by thrombus or embolus, when the patient may have to depend for his life on a desperate emergency operation or, should a smaller vessel be involved, on palliative treatment which may in some cases be contributory to recovery.

The Bed-bug as a Housing Problem

By A. W. McKENNY HUGHES, D.I.C., F.R.E.S.

(From the *Medical Officer*, Vol. LII, 17th November, 1934, p. 203)

CONSIDERATION of the bed-bug as a housing problem must be subdivided under two heads: (1) precautionary measures to be taken with regard to new housing schemes, and (2) the disinfection of old buildings, many of them in private ownership, which, while structurally sound, are bug-infested and must be disinfested whilst the tenants remain in occupation. The latter is, to my mind, by far the bigger and more difficult problem to tackle.

Let me now deal with the first part of the problem. Prevention of infestation of new houses is in no way difficult, though some people may say that it is impracticable on the grounds of expense. Tenants' furniture should be fumigated in transit to the new house with hydrocyanic acid gas in one of its forms, or alternatively all furniture should be fumigated in the new house within a week of arrival. This latter method necessitates a clearing house, where people whose houses are being fumigated can spend the night; the institution of such a house would, I think, be of great advantage in any bed-bug campaign. As far as possible, families should be encouraged to buy their second-hand furniture before their move, so that

it can be fumigated with the rest; but if not, I should like to see a by-law passed with regard to its sale, since a large percentage of reinfestation is due to this class of dissemination.

Let us now consider the design of new houses. In the first place, woodwork should be reduced to the minimum. Skirtings may be replaced by cement rendering down to the floor; door frames can either be of metal or wood, and the place of the architrave and mouldings taken by adhesive tape, placed over the crack, which is bound to develop, and painted over. Pipes should be carried clear of the wall, and where they pass through the floor or ceiling, precautions must be taken to prevent access to the crevice so formed, or they should be thoroughly chased in. Picture rails should be replaced by pin hooks or by metal slots incorporated in the plaster which, although they provide harbourage for bugs, can nevertheless either have paraffin poured into them, or be cleaned out by a piece of wood exactly fitting the slot.

Hot-water systems should be as near the bath-room as possible, to avoid unnecessary piping, and all such fixtures and fittings should be incorporated in such a way as to give the minimum of harbourage. A little imagination and common sense will do a great deal in this direction. Particular thought should be given to the foundations, to ensure that there shall be no subsidence of the structure; a few more shillings here may save pounds later on. Floors, walls and ceilings should be of such materials as to provide the minimum of cracking or harbourage; thus, beaver boards overlaid with tongued-and-grooved flooring should be avoided, or bugs will harbour between the two. Certain forms of sound-deadening materials, too, are admirable harbourage for bugs. In short, the bug likes warm, undisturbed cracks and crevices to live in, where it can get either its back and belly against some rough surface or where it can put its shoulder to the wall; therefore, avoid as far as possible providing comfort and even luxury for this pestilential creature.

Now let us consider the second and more difficult part, namely, the disinfection of houses structurally sound in which the tenants will have to remain. Hydrocyanic acid gas will undoubtedly clear such premises of bugs, but the houses must be vacated for twenty-four hours, and those on either side for about seven and a half hours. This necessitates finding alternative accommodation for the tenants. It may be possible to develop some system whereby the whole operation may be safely undertaken in a day, but that is not practical politics as yet. To my mind it is no good doing one or two houses in the middle of a heavily-infested terrace, as the bugs are certain to return from either side. If disinfection is to be done, it must be done thoroughly or not at all; skimpy jobs bring the whole campaign into disrepute. As to cost, while this is undoubtedly high, you have got to consider this in relation to other methods not so effective which have to be done over and over again and which are, when all is said and done, only palliatives. Also there is the far more serious aspect that by leaving this reservoir of bugs, you always have a ready source from which these insects may be taken to new areas. The best method then that we know of so far is the use of hydrocyanic acid gas, systematically applied. In the hands of experts it can be used with safety, but in the hands of untrained only partially trained workers it is extremely dangerous and fatal accidents are likely to occur. Tenants can be fumigated as a whole or a few houses can be taken at a time; but what I would emphasize is that no fumigant leaves any deterrent to bugs behind, and therefore terraces should be treated up to the natural break, such as a passage or street, and not stopped in the middle. Another fumigant, very much as effective as HCN and so toxic to man, is ethylene oxide (Ethylene-oxide-carbon-dioxide). Unfortunately,

somewhat more inflammable and explosive than HCN, but again, experts can handle it safely. In cost it is relatively the same as HCN, but it can not be used effectively at low temperatures. It has the advantage that it can be used without having to empty the houses on each side; the process takes roughly twenty-four hours. Then we come to that old favourite, sulphur, which when used at a rate of six pounds per thousand cubic feet twice at an interval of three weeks will be about 85 per cent effective and no more. The various processes are so well known that I need not describe them to-day. Finally, there are various sprays which give off a vapour, such as those with basis of orthodichlor-benzene or other chlorinated hydro-carbons. Orthodichlor-benzene used by itself is only about 50 per cent effective, and possibly not quite as much, but the mixtures of fifty-fifty orthodichlor-benzene-carbon-tetrachloride or fifty-fifty orthodichlor-benzene-methylated-spirit seem promising. All these sprays that I have mentioned necessitate the use of a gas mask when applying them, and carbon tetrachloride has at various times been known to cause liver trouble in those handling it, so that special care is necessary. One disadvantage of all these mixtures is the smell left behind by the orthodichlor-benzene, which will persist for very nearly a week, though it is quite harmless. Carbon-tetrachloride and some of the other chlorinated hydro-carbons also act sometimes as paint solvents. Research is being carried out with regard to these mixtures, and we shall hope to know more about them before very long. At present they have only been used more or less haphazard in houses and tenements and not under scientific control, so that there are no exact data available with regard to concentration, toxicity, and so on, but these experiments have indicated that this would appear to be a profitable line to follow.

A great deal has been heard about reconditioning new houses, and in many cases this has been done without taking into consideration the elimination of bugs. In so doing it seems to me that good money has been thrown down the drain, and the houses thus reconditioned still remain slums. In all cases where this class of work is about to be undertaken, the houses should be fumigated with HCN before any reconditioning takes place and, naturally, the same proviso with regard to the fumigation of one house in the middle of a bug-infested terrace holds good here.

Another aspect which deserves consideration is the disposal of material from bug-infested houses demolished under clearance orders. There is no doubt that the woodwork from such houses is liable to be an important factor in the dissemination of the bed-bug, not only as firewood, but in various other ways. It is possible that the brick and plaster work may also be a source of danger, though the evidence here is conflicting. In any event, precautions should be taken before this material is disposed of to a contractor. This can be done either by fumigating the houses before they are pulled down or, less satisfactorily, by means of the blow-lamp, which obviously cannot be entirely relied upon.

Any large-scale fumigation scheme must have running concurrently with it a cleanliness campaign, since, as there is no deterrent effect left by the fumigant, houses will sooner or later become reinfested unless measures of cleanliness are taken to avoid this. All forms of publicity should be used to make the population 'bug-minded', so that the presence of the insect is not considered as a social stigma and something to be hidden, but as a misfortune from which any of us may suffer, and which all of us have got to help to alleviate. With this end in view, publicity by the press, by means of circulars from local authorities, by special stalls at health weeks and by lectures and films, should play its part. The more the bug is talked about the easier will be the task of those who are responsible for its eradication.

Intensive Liver Extract Therapy of Sprue

By C. P. RHOADS, M.D.

and

D. K. MILLER, M.D.

(Abstracted from the *Journal of the American Medical Association*, Vol. 103, 11th August, 1934, p. 387)

THE effective treatment of sprue is a problem of considerable practical importance in spite of the fact that therapeutic methods which are occasionally successful have been at hand for many years. One serious difficulty lies in the fact that different individuals, presenting an apparently identical clinical picture, manifest wide variations in the amount of specific therapy that they require to effect clinical cure. Moreover, the available information regarding the treatment of sprue is confusing, since the various therapeutic procedures in use appear to be so unrelated and the clinical results obtained from them have been so inconstant that it has seemed impossible to draw up a general rule of treatment that would be applicable to all cases.

More detailed analysis of the existing therapeutic methods in the light of present knowledge makes it clear that a general rule of treatment can be formulated and, furthermore, that from the therapeutic results an understanding of the etiologic mechanism of the disease syndrome may be obtained. Such an understanding is of importance in treatment, since without it various therapeutic procedures seem to be purely empirical; and when doubt as to the rationale of a procedure exists the determination to carry it through to the desired end is frequently wanting.

Prior to 1927 the treatment of sprue was almost entirely dietary. The accepted policy was to restrict the intake of fat and of carbohydrate and to depend on different single and apparently dissimilar food materials as the principal sources of nutrition. Thus in turn liver diets, meat diets, milk diets, banana diets and strawberry diets were all recommended and were frequently effective when employed early in the course of the disease. Complete and permanent cure occasionally followed such treatment but early and severe exacerbations were the rule and a stage of the disease was eventually attained at which dietary measures were ineffective.

Baumgartner showed that the feeding of these diets was specific in promoting hæmatopoiesis. He applied to sprue anæmia a procedure devised by Minot and his associates for evaluating the effectiveness of specific therapy in pernicious anæmia. The method was based on the fact that the percentage of reticulocytes in the circulating blood increased very markedly at the onset of a true remission. Reticulocyte rises were induced by feeding to individuals with sprue anæmia certain diets which were known to be effective in the treatment of that disease but which did not contain liver or other material known to be curative in pernicious anæmia. This observation was evidence that some constituent of the diet was specifically required for hæmatopoiesis in sprue anæmia and that this dietary constituent was not the liver function so effective in the treatment of pernicious anæmia. This difference in the response to therapy was the more incomprehensible when the striking hæmatologic similarities between the two anæmias were considered. Two problems were then at hand; first, to ascertain the presence of some common factor in the diets known to be effective in the cure of sprue and, second, to show the relationship of such a common factor to the substance effective in pernicious anæmia, a disease that is symptomatically and hæmatologically similar to sprue.

A more detailed knowledge of nutrition makes it clear that the seemingly dissimilar diets do possess one factor in common: a relatively high content of water-soluble vitamin. Since this appears to be the only common factor, it seems probable that the effects obtained in the treatment of sprue by feeding these diets are due to the water-soluble vitamin which they

contain. It is an established principle in the study of nutritional factors that, if a demonstrable physiologic effect can be induced by feeding any one of a variety of substances in which only one particular vitamin is common to all, the effect will occur only in the presence of a deficiency of that vitamin in the body of the test animal. Since several different diets are irregularly effective in the treatment of sprue and these diets contain only the water-soluble vitamin as a common factor, it seems probable that a lack of that vitamin exists in certain cases of the disease. Furthermore, the existence of such a lack suggests that it is perhaps causal; that is, that sprue is a disease due in some instances at least to a deficiency of some fraction of the water-soluble vitamin complex. Since dietary treatment is not always effective, however, it follows that in other instances one or more additional or complicating etiologic factors are involved. Studies of the factors concerned in the etiology of pernicious anemia, a disease similar in many respects to sprue, have given the clue to the nature of the complicating factors concerned in the etiology of the latter disease.

In 1925 Minot and Murphy showed that whole liver was specifically effective in the cure of pernicious anemia. Bloomfield and Wyckoff fed whole liver to individuals suffering from sprue and in 1927 published an account of clinical cures resulting from such treatment. In the following year West reported remissions following the treatment of sprue with that fraction of liver which had been shown by Cohn, Minot and their associates to be effective in pernicious anemia. Liver extract then, as well as diets rich in the water-soluble vitamin, may be therapeutically effective in sprue. To establish the etiologic similarity between sprue and pernicious anemia, it remained only to prove that the water-soluble vitamin could induce remissions in the latter condition. Such an effect was suggested by the studies of Castle and his associates, which showed that a dietary constituent contained in beef muscle was acted on by a substance present in normal gastric juice to produce a third substance potent in producing remissions in pernicious anemia. The gastric juice of patients with the disease was not effective in forming the hæmatopoietic principle by interaction with the dietary factor. Hence, a deficiency in the gastric secretion was clearly causative of pernicious anemia. Other investigators showed that the livers of patients with pernicious anemia who lacked adequate gastric secretion were devoid of the hæmatopoietic principle present in normal livers. It was apparent that the product of the interaction of a dietary factor and normal gastric secretion was stored in the liver, where it was available for clinical use as liver extract.

It appeared from these investigations that a dietary constituent as well as normal gastric secretion was required for hæmatopoiesis. In 1931 Castle and his associates pointed out that a disease similar to pernicious anemia should develop if there was an insufficient intake of the dietary constituent, a defect of the gastric juice or defective absorption of the product of the interaction of these factors. Sprue was similar to pernicious anemia and was due in some instances to lack of a diet rich in the water-soluble vitamin. Clearly, if the dietary factor involved in the causative mechanism of pernicious anemia should be shown to be the water-soluble vitamin, the link between pernicious anemia and sprue would be established.

The next step was to establish the dietary factor as being related to the water-soluble vitamin. Wills described remissions induced in cases of tropical macrocytic anemia by feeding an extract of yeast, which was rich in that vitamin. Castle and Rhoads observed similar responses resulting from the use of the same yeast extract in cases of sprue. This was confirmatory evidence that a relatively simple preparation rich in vitamin-B complex was effective in that disease. An exactly similar effect was shown by Strauss and Castle to occur if the same yeast extract

was incubated with gastric juice and fed to patients with pernicious anemia. Reticulocyte rises and improvement of blood values occurred uniformly. Neither the yeast extract nor the gastric juice was effective alone. This indicates that the dietary factor, given as meat in the original experiments of Castle, was contained in a yeast extract rich in the water-soluble vitamin and that an interaction with gastric juice was required for it to be effective in hæmatopoiesis in pernicious anemia. Thus the only difference between certain cases of sprue and of pernicious anemia was that a substance rich in the water-soluble vitamin was therapeutically effective *per se* at least in certain cases of sprue, whereas it was effective in pernicious anemia only after it had been incubated with normal gastric juice. The dietary factor in the two conditions was the same. Simple dietary lack, while apparently causative in certain instances, was clearly not the only factor involved in the production of all cases of sprue.

Since symptomatic similarities between sprue and pernicious anemia exist, and since orally administered liver extract, a material effective in pernicious anemia, was occasionally effective in cases of sprue, which had failed to respond to diet alone, it seemed probable that the lack of a gastric secretory factor might contribute at least to the causative mechanism of sprue in the way in which it had been shown to be causative in pernicious anemia. The observation by Rhoads and Castle of the similarity between the pathologic alterations of the bone marrow in the two conditions is further evidence that they possess some etiologic factor in common. The study by Castle and Rhoads of a large number of cases of sprue in Puerto Rico showed that the gastric dysfunction obtaining in pernicious anemia did play a part in the production of symptoms in certain instances. This was clear from the fact that in some cases the addition of normal gastric juice to substances rich in the water-soluble accessory food factor was required before a remission could be effected. This was evidence that there was a lack of anti-pernicious-anemia factor in the gastric juice of the patients tested. In the same publication it was reported that in other instances remissions could not be induced even though both the dietary factor and the gastric factor were supplied to the intestinal tract. This was also the case when liver extract, a material supposed to represent the product of the interaction of those two factors, was given by mouth, although when a much smaller amount of liver extract was administered parenterally, maximum responses were obtained. As suggested by Castle, for pernicious anemia this fact can indicate only that the effective material either was not absorbed from the intestinal tract or was broken down in it. The former hypothesis was considered to be the most probable, since sprue may result from surgical intervention with the absorbing surface of the bowel; moreover, sprue is frequently associated with secondary deficiencies of such dietary constituents as calcium and iron, elements not likely to be destroyed in the intestinal tract.

It appears, then, that clinical sprue may arise in three ways; by dietary lack, by lack of the gastric enzyme that is absent in pernicious anemia, or by inability to absorb the product of the interaction of the first two. Clearly, any one of the three factors may be causative or any combination of the three may exist. Furthermore, differences in the relative importance of the part played by each of the three might account for variations in the clinical manifestations.

In view of the facts presented, it becomes clear that the desideratum in the treatment of sprue is to place the product of the interaction of the dietary factor and the gastric enzyme, that is, liver extract, as near to the site of utilization as possible in as large amounts as may be required. Our purpose in this communication is to indicate what parenteral route is most

effective and what amounts of material are required to induce remissions in the most refractory cases. If methods effective in those cases were to be applied as a general rule in the treatment of all, therapeutics would become simplified and the period of the patient's incapacity would be materially reduced.

Comment

The four cases of sprue reported [case reports omitted] all failed to respond to some form of specific treatment but did finally improve under intensive parenteral therapy. They were the only ones in a series of twelve cases of sprue similarly studied and treated in which a clear-cut comparison between different methods of treatment could be drawn. In all four refractory cases a steady, progressive increase in the severity of the disease had taken place in spite of supposedly adequate therapy employing agents that were known to be specifically effective. When moribund, all were finally treated with massive doses of liver extract, parenterally administered, and in all a prompt, dramatic and complete remission was effected. All have been maintained in good health by means of injections of liver extract at intervals not exceeding one month.

In addition to being completely refractory to any sort of oral therapy, two of the individuals had received persistent and supposedly adequate parenteral treatment without improvement. It thus appears that a well-defined threshold requirement for liver extract exists in certain cases of sprue, a threshold that must be exceeded before a remission can be established. When such a refractory case is encountered intravenous therapy is indicated, not only because it is more effective in raising the concentration of the required substance in the blood stream but also because it is the only route by which the required amount of material can be administered without causing serious discomfort and perhaps disability to the patient. Any patient with sprue admitted for treatment now receives intravenously an amount of liver extract derived from 50 grammes of liver each day until a clear-cut remission has been established.

The liver extract preparation found to be most effective is a relatively simple, unconcentrated product. Evidence is at hand that a certain loss of activity results from too great refinement and concentration. Patients with sprue have failed to improve on intramuscular injection of a large amount of a highly refined and concentrated product although a full remission has been effected by the use of a much smaller amount of material more simply prepared.

The mechanism of the production of the increase in the threshold requirement for liver extract is at present unknown. An analogous situation may be observed in animals, however, in experimentally-induced disease states due to the lack of certain accessory food factors. One of these experimental deficiencies is 'canine black tongue', a condition considered by Goldberger and Wheeler similar to pellagra in human beings and due to a lack of the heat-stable, water-stable vitamin. In black tongue a refractory state may be induced if treatment is kept at the minimum required for preservation of life during repeated acute attacks. Eventually no amount of material rich in water-soluble vitamin will effect improvement, although a minute amount of the same substance is prophylactically effective.

The amount of treatment required to maintain a person with a high threshold requirement in good health, once a full remission has occurred, varies widely in different individuals. In one instance intramuscularly administered liver extract is required at intervals of two weeks. If the treatment is delayed, gastro-intestinal symptoms recur and persist until liver extract is administered. In other individuals, treatment once in thirty days is sufficient to prevent recurrence.

As previously discussed, the effectiveness of liver extract in the treatment of sprue, coupled with other

known facts, clarifies the etiologic mechanism of the disease. The efficacy of intensive treatment of cases refractory to less adequate measures is further evidence of the specificity of the effect of liver extract. The requirement of certain individuals for very large amounts of effective material administered parenterally is evidence of a threshold requirement that must be exceeded before a physiologic response can occur.

The emphasis that has been placed on the purely hematologic responses of pernicious anemia to liver has obscured the fact that corresponding improvement of the lingual and gastro-intestinal symptoms occurs. This was pointed out by Minot and Murphy in their original communications and has been commented on by others. The idea of treatment by diet of a gastro-intestinal disorder, such as sprue, is so thoroughly ingrained in the medical consciousness that it is difficult for it to abandon the conception of some beneficial quality of the diet, simply as a regimen. The foregoing discussion should serve to indicate that the occasional effectiveness of diet in the treatment of sprue is largely based on its ability to supply the water-soluble vitamin. Diet is, at best, an uncertain method of obtaining 'liver extract' for the internal economy of the organism. By the use of parenteral liver extract the obstacles of dietary defect, gastric dysfunction and intestinal malabsorption are at once effectively surmounted.

Summary and conclusions

1. Four out of a series of twelve cases of sprue were refractory to ordinary effective treatment. Clinical cure followed intensive parenteral liver extract therapy.
2. The use of liver extract in sprue is indicated by the etiologic mechanism of the disease.
3. Sprue frequently requires much more intensive treatment with liver extract than does pernicious anemia.
4. The frequent parenteral administration of large amounts of liver extract is the therapeutic procedure of choice in sprue and should be continued until a remission is established.

The Treatment of Gonorrhœa in the Female

By EMILY DUNNING BARRINGER, M.D.

(Abstracted from the *Journal of the American Medical Association*, Vol. 103, 15th December, 1934, p. 1825)

The successful treatment of gonorrhœa depends largely on a thorough understanding of the underlying pathologic condition and on making a careful diagnosis before any type of treatment is instituted. The diagnosis should be established by a positive finding of the gonococcus by smear, culture or complement-fixation test.

Gonorrhœa in the female can be likened in many ways to a typhoid infection. Taken as an acute infection in a woman or girl who has previously had normal pelvic organs, one may expect a fairly definite clinical course in an ascending infection, which passes up above the internal os. Thus it will run its course for a period of six to seven weeks, reach its clinical peak and then begin to subside, so that at the end of twelve to fourteen weeks one may look for a cessation of the clinical symptoms and the organs may return to approximately their original conditions and be free from the gonococci. This is barring complications. But gonorrhœa similar to typhoid is prone to complications.

Another factor to be considered is whether the gonococcus is the only offending organism or whether other pyogenic organisms are present which give rise to a so-called mixed infection. It is this admixture of other organisms which is usually found in the complications and especially the prolongation of the complications. Still another factor to be considered is the resistance of the patient, and it is the careful understanding and evaluation of all these various

considerations that underlie intelligent treatment of gonorrhœa in the female.

Gonorrhœal cases clinically fall into three groups, acute, subacute and chronic, and the treatment will vary with these different stages.

Thus in the acute stage the main indications are for absolute rest, lack of trauma and treatment directed toward preventing the spread of the infection. Ill-advised douching and medication of the cervix in very acute cases may result in just the outcome one is trying to prevent. It is debatable whether, in these very acute cases, rest in bed, with carefully ordered general medical supervision, and only local cleansing of the external genitalia do not lead to recovery as satisfactorily without local treatment.

However, it is my routine procedure in acute cases in which it is obvious that the infection is ascending to give the patient, in addition to absolute rest and lack of trauma, mild heat in the form of medicated douches under low pressure and the administration of a solution of mild silver protein by gentle application to the cervix and urethra. The greater degree of heat, 130°F. as given by the Elliott machine, seems unwise during the acute stage because of the softening and relaxation of the cervix, thereby opening up one of the natural barriers to the spread of infection.

In the subacute stage the complications are usually found as possible gonorrhœal infection of the rectum; thus it is not uncommon to have Bartholin or Skene's glands and ducts involved. These in turn will often subside spontaneously in the course of the routine treatment of the infected urethra, and it is better in my judgment not to attempt any local treatment of these glands until expectant treatment has failed. It is in this stage that greater degrees of heat may help, and this may be given by the medicated douche up to 116 to 118 degrees or with the Elliott machine, whereby the heat may be pushed up to 130 degrees.

With the chronic stage it is important to try to estimate what organisms are responsible for the continued symptoms. Occasionally symptoms continue because of a persistent virulent infection by the gonococcus. It is much more likely, however, that the gonococcus has passed out of the picture and that the symptoms are resulting from infection with the streptococcus or actinomyces. If the chronic symptoms are due to the gonococcus, especially perimetritis, continued heat therapy, such as prolonged hot douching, Elliott-machine treatment, or diathermy, will undoubtedly be effective. If the streptococcus or actinomyces is the offender, probably little will be accomplished.

It is in this stage that one is confronted with complications that have not yielded to expectant treatment and it becomes necessary to consider radical measures.

Thus, intractable Skene's glands should be irrigated with an antiseptic solution through a small malleable tipped needle made for this purpose. If this is not efficacious, the gland should be obliterated by the passage of an electric cautery needle down through the duct.

Periurethral abscess should be treated expectantly by careful massage, the abscess being emptied into the urethra and the sac filled with an irritant antiseptic solution. These should be opened surgically only when this expectant method has failed.

If Bartholin glands do not subside with expectant treatment, careful resection should be done, preferably by the intravaginal route, as described elsewhere.

Persistent lesions of the cervix may call for radical treatment. If there are chronic sluggish erosions, it is important to know by culture what organisms are responsible. If, as is often the case, actinomyces is responsible, iodine therapy should be given by mouth and locally.

Careful coagulation or cauterization by the electric needle is often indicated, and in selected cases the ionization of the cervix is valuable. But it is always

practical to stress again the importance of selecting these cases with greatest care, for an ill-advised operation on the cervix of a recent gonococcus patient may stir up a fulminating salpingitis.

Operative intervention on tubes and ovaries infected by the gonococcus should be done only for urgent or definite reasons and should be avoided whenever possible. Spreading gonococcal peritonitis is rare but may be fulminating in character, especially in young girls, in whom it may simulate a ruptured appendix and calls for prompt operation. The perimetritic exudate of the acute and subacute stages may become completely absorbed. The sealed off gonorrhœal pyosalpinx soon becomes sterile pus and may subside, and the possible functional return for these damaged organs is not yet fully appreciated.

Can the curative process be hastened and impending complications aborted? Will increase of the antibody formation, such as administration of vaccine accomplish this? There is considerable division of opinion in regard to the efficacy of vaccine therapy. A number of authors find little value in this form of therapy, while others approve its use. Demonchy advocates enormous doses of stock or autogenous vaccine and reports satisfactory results. He states that quite a number of cases are cured by a few injections without local treatment. However, the stage of the infection seems to make a difference, for in twenty-five cases of acute gonorrhœa in the male treated by the Demonchy vaccine, the results were not impressive, as the number of cases cured were small, the time required for cure was longer than the average and there was a tendency to stir up an arthritis, which is a fairly rare symptom.

CONCLUSIONS

1. Vaccine therapy is not a specific for the cure of gonorrhœa. It is, however, probably a very valuable form of treatment in the acute and subacute stages of the disease. This is probably true also in chronic cases in which the main offending organism is the gonococcus. It is probably not of value in cases due to 'mixed' infection.

2. In the acute and subacute stages, vaccine therapy will probably shorten the period of hospitalization. However, the great drawback of severe reaction from this treatment, especially with large doses, is to be considered.

3. It is questionable whether very large doses are justifiable, because of these reactions.

4. Probably vaccine therapy in smaller doses combined with indicated routine treatment would be a more desirable type of treatment.

5. Vaccine therapy is of sufficient importance to warrant further careful study into dosage, complement-fixation reaction, and tests for proof of cure.

A New View of Psoriasis

(From the *Lancet*, 15th September, 1934, p. 605)

A NOTABLE contribution towards the solution of the problem of psoriasis, perhaps the greatest and most elusive in the domain of dermatology, appears to have been made by Prof. O. Grütz, of Wuppertal-Elberfeld, in a lecture given to the Berliner medizinische Gesellschaft on June 6th last and published in the *Deutsche medizinische Wochenschrift*, 13th July, 1934, p. 1039. His hypothesis is based on the histological findings in a case of the disease in which diabetes with hyperlipidosis and hypercholesterinæmia were superadded. It was shown by special fat-staining methods that the lipid substances which had been excreted into the skin, with the production of characteristic xanthoma nodules, were present in great abundance in the parakeratotic scales which are the clinical sign manual of psoriasis. This was no new discovery, for excess of cholesterol and lipid substances had long since been recorded in psoriasis scales by Unna, Linser, and others. Its significance had, however, been ignored. Grütz reinvestigated the point, went a step further, and in collaboration with

a biochemical colleague Prof. Bürger, of Bonn, has now examined the lipoidal content of the blood of a large number of psoriatics. This had previously been done by Puley and Brill, but they appear to have contented themselves with only one or two examinations of each case and to have found no abnormality. A physician suspecting hyperglycæmia would hardly be satisfied with a single negative blood examination; the Grütz-Bürger series of blood examinations appear to have been conducted on the lines of those which are now in use in the diagnosis and management of cases of diabetes before a routine has been definitely established.

In brief outline the procedure consists in giving 5 g. of cholesterol in 100 g. olive oil to the fasting subject, and then withdrawing 50 c.cm. of blood at 4-, 8-, and 24-hourly intervals for examination of the variations in the fat and lipid of the untreated serum. The alteration in psoriatics as compared with the normal is said to have averaged a 40 per cent increase of total serum-fat content, together with a pronounced excess of cholesterol and phosphatide compounds. This figure is high enough to render recognition of the characteristic blood state a relatively simple matter, and should make correspondingly easy the task of the pathologists who will be investigating the justification of the claims put forward. If the results confirm Bürger's work we shall have to regard psoriasis as due to a disturbance in the metabolism of fats, and the pathogenesis of the disease will afford a close resemblance to that which now pertains for xanthoma. Right or wrong the hypothesis presents us with a key which appears to fit many of the subsidiary locks in the prison which has guarded the secret of psoriasis. On the side of its undoubted hereditary tendency it may be urged that just as diabetes—a carbohydrate dyscrasia—may be familial, so we may have a congenital inability to deal with the metabolism of fats. The effect of arsenic in psoriasis may be due to its influence on general metabolism, including that of fats—the excessive formation of which is sometimes stimulated by arsenical medication. No one would deny this possibility, for thyroid and other endocrine products have been generally

accepted as having a favourable influence on the course of the disease in many instances. The benefit of local treatment with tar, chrysarobin, cignolin, and a host of other substances can similarly be explained as a local chemical effect—possibly of oxidation type—on the lipoidal and other fatty substances present in the lesions, while the recurrences after local treatment on this basis require no explanation at all. Nor would it be surprising that the effect of sunlight, ultra-violet light, x-rays, and other physical methods should only be temporary.

The scheme of treatment suggested by Prof. Grütz is presented in a very simple table. Fats, oils, cream, butter, cheese, and margarine are banned, and it should be the doctor's aim to reduce fat intake, which cannot be altogether excluded, to a maximum of 20 g. in the adult and 10 g. in children per day. Yolk of egg, in view of its cholesterol content, should also be excluded, although the white is allowed. Such a diet should offer little difficulty even in domestic circles, and calorie requirements are amply covered by carbohydrate and protein intake. There appears to be little danger of serious loss of weight even after months of fat deprivation, and no mention is made of nutritional effects due to the loss of vitamin D. It is quite likely that just as in most cases of hyperglycæmia there is an individual threshold, it would be possible to ascertain the fat and cholesterol tolerance by trial and experiment for each patient suffering from psoriasis, so that he would not necessarily have to endure a completely fat-free diet for the rest of his life. It is evident, so far as the work has gone, that dietary treatment does not and is not expected to cure psoriasis. But if it renders latent the inherent dyscrasia in the metabolism of fats, a patient conforming to the principles laid down by his doctor might reasonably expect to remain immune from attack. The periods of remission, followed by recurrences, which have hitherto been the disheartening fate of victims of this disease will make it impossible to assess the value of this new form of treatment for some years; the case records of Prof. Grütz's series are not given in his lecture, but are promised for early publication.

Reviews

A PRACTICAL TREATISE ON DISEASES OF THE SKIN.—By Oliver S. Ormsby, M.D. Fourth Edition. 1935. (With revision of the Histopathology in this edition by C. W. Finnerud, B.S., M.D.). Henry Kimpton, London. Pp. xiii plus 1288. Illustrated with 619 engravings and 3 coloured plates. Price, 50s.

THIS book has nothing to recommend it in preference to other well-known textbooks on the subject.

It gives stereotyped descriptions of skin diseases arranged under the usual headings with copious references throughout the text to the opinions and advice of all the well-known authorities, but nowhere was it noticed that the author expressed any opinion of his own. In fact it gives the impression of being a compilation from numerous writers rather than the result of long and wide personal experience of the author in the study of dermatology with a judicious admixture of information from other sources such as a textbook usually consists of. It is considered unnecessary to give sketchy descriptions of the exanthemata because such diseases are always fully dealt with in textbooks of medicine.

In some instances the word *recent* is rather overworked; for example its use in describing the treatment of ulcerating granuloma of the pudenda with tartar emetic is distinctly misleading.

There are numerous illustrations from photographs some of which are of educational value, but others such as the one on p. 625, depicting chondrodermatitis nodularis chronica helioides, would be of little assistance in making a diagnosis, and the provision of only three coloured plates in a book of this size and price is rather niggardly.

It is a book that might be of use to the general practitioner for reference.

P. A. M.

MEDICAL RESEARCH COUNCIL. (Special Report Series, No. 195.) Active Immunization against Diphtheria. Its Effect on the Distribution of Antitoxin Immunity and Case and Carrier Infection.—By Sheldon F. Dudley, Percival M. May and Joseph A. O'Flynn, with a note by J. Orr Ewing. 1934. Published by His Majesty's Stationery Office, London. Pp. 140. Price, 3s.

'ELEVEN years ago the Council published a report of an investigation made at Greenwich Hospital School by Surgeon-Commander Sheldon F. Dudley, R.N., on "The Schick Test, Diphtheria and Scarlet Fever". Since that time the work has been continued, so that the present report and its predecessor together form a unique record of twelve years' continuous study of diphtheria, especially in its immunological aspect, among a semi-isolated community where practically

all factors such as social class, nutrition, occupation, and environment have remained constant.

The acceptance by the school authorities of inoculation against diphtheria in 1928 introduced a variable which afforded an opportunity for further research in that it allowed a close comparison of natural immunity, acquired by a community in which diphtheria was endemic, with a condition of immunity artificially induced by inoculation. That this opportunity for a properly controlled investigation was fully utilized is tested by the present report.

It is the introduction of this variable which, for instance, allows the authors to make the deduction that three doses of diphtheria toxoid can produce in three months as high an immunity as three years' residence in a community where diphtheria is endemic. The natural process was of course accompanied by a high incidence of diphtheria, whereas in the artificial immunizing process no clinically recognizable diphtheria developed. Thus, not only was there a great saving of time in producing the degree of immunity, but also a marked improvement in the general health.

It is an impressive fact that as the result of this experience the authors can claim that artificial immunization, at least in a community where sources of the infection are constantly present, is an almost certain protection against recognizable clinical diphtheria. On the other hand, the demonstration that active immunization by inoculation is no protection against diphtheria-carrier infection, and may under certain conditions increase the number of virulent carriers, shows the limitations of this method of protection against diphtheria when it is only partially carried out in a community.

Either in its purely academic aspect as a biological study of the interactions of the environment and two species of organism—man and the diphtheria bacterium—on each other, or as a practical study of immunity against a deadly disease, the present publication can be regarded as a notable contribution to knowledge.

We feel that we cannot do better by way of explaining the scope of this book than to give the above quotation from the preface. Diphtheria is often very troublesome in schools in the hills in India, and we recommend this special report to those who have to deal with the problem.

DEFINITE DIAGNOSIS IN GENERAL PRACTICE.—

By W. L. Kitchens, M.D. 1934. W. B. Saunders Company, Philadelphia and London. Pp. xlv plus 1000. Price, 45s.

It is very hard to accept this book as a serious contribution to medical science, and yet reading Dr. Musser's introduction one must concede that, if the book is used as it is meant to be used, it must make for more accurate examination of the patient and therefore must tend towards the betterment of the science of diagnosis, and not towards its reduction to the status of a jig-saw puzzle, as one is rather inclined to think when one first takes up this book.

As the arrangement of the book is, in our experience, quite unique we should perhaps describe it. It is divided into two parts—symptoms and diseases. There are 513 symptoms or diagnostic signs, to each of which a page is devoted; on this page is a full list of diseases with which this sign or symptom is associated. Conversely, in the second half of the book there are 407 diseases on 407 separate pages and on each page there is a list of the symptoms, signs, and clinical laboratory findings associated with the particular disease. To ensure quick cross reference all diseases, symptoms, signs, etc., are given numbers corresponding to the pages on which they are dealt with. Take an example; you find that a patient has a tricuspid murmur; you look up 'murmur, tricuspid' in the symptom index and are referred to p. 323, where you find a list of thirteen diseases in which a tricuspid murmur may occur; you then turn to the second part

of the book and look up these thirteen diseases in turn to see which fits in with the other symptoms and signs you have observed in your patient. Or if you really wish to reduce it to the jig-saw puzzle level, you write down the numbers of the diseases you find on p. 323; you take one by one the other signs and symptoms you have observed, write down the numbers you find on their pages, select the number that recurs most often, look up the corresponding disease, and there you are!

Yet, used intelligently, the book presents great possibilities.

ELECTROCARDIOGRAPHY.—By Chauncey C. Maher, B.S., M.D. 1934. Baillière, Tindall and Cox, London. Pp. xlv plus 250, with 95 illustrations. Price, 18s.

IN spite of the numerous books on electrocardiography that have recently appeared dealing with the clinical aspects, the author feels that there is still 'need for a treatise on electrocardiography for use by the general practitioner, the medical student, and the specialist exclusive of the cardiologist'. The value of electrocardiographic examinations in the diagnosis of the heart diseases has recently been much appreciated and a detailed knowledge of the modern conception of the cardiovascular disease is absolutely essential. It may safely be said that this book makes as good a presentation as can be done in a volume of this size.

The first few chapters deal with the clinical concepts of the heart diseases and explain the cause of the normal electrocardiographic deflections and their relation to physical and physiologic processes in the heart. The author then proceeds logically to an analysis of the abnormal cardiac disturbances and their effect on the electrocardiograms. The whole problem is presented in an interesting fashion and the methods for the scientific evaluation and arrival at a diagnosis are systematic. The syndrome of symptoms, prognosis and treatment have been accurately described. Some suggestions on the routine interpretation of electrocardiograms are very desirable and the author has attempted to outline a scheme at the end of the book.

It is a simple, concise and yet a comprehensive treatise by an author who can lay claim to a very large experience. It is accurately written and sufficiently illustrated, though it may not be quite as useful to the beginners as some of the other elaborately detailed works. Throughout the book the orderly arrangement is a great aid to the reader, and physicians will find in the volume a most satisfactory and valuable diagnostic help.

R. N. C.

A HANDBOOK OF GYNÆCOLOGY.—By B. Solomons, B.A., M.D. (Univ. Dub.), F.R.C.P.I., F.C.O.G., M.R.I.A. Third Edition. 1934. Baillière, Tindall and Cox, London. Pp. xlv plus 368, with 250 illustrations. Price, 15s.

THE third edition of this well-known book on gynæcology is welcome, and will be appreciated by both students and practitioners.

The author has a clear and forceful style. He is dogmatic in his opinions and illustrates them excellently. It is a pleasure to see illustrations clearly indicating the meaning of the text and eliminating redundant explanations.

It would be fair to describe the handbook as 'compressed gynæcology' strongly flavoured with the author's opinions. It is more welcome for this as a student will be left in no doubt whatsoever as to what type of treatment or operation is required; dogmatic statements are always welcome, and are particularly valuable when backed by such experience as the author's.

The chapter on x-rays and radium treatment deserves special commendation. It contains a clear explanation of the methods adopted at various clinics and makes a difficult subject easy of understanding.

Containing a wealth of information in compressed yet readable form, the book will be of value to students studying for examinations, and to practitioners as a book of reference.

S. N. H.

THE TREATMENT OF COMMON FEMALE AILMENTS.—By F. John McCann, M.D. (Edin.), F.R.C.S. (Eng.), F.C.O.G., M.R.C.P. (Lond.). Third Edition. 1934. Edward Arnold and Company, London. Pp. viii plus 379. Price, 12s. 6d.

TEXTBOOKS deal with typical cases; unfortunately all cases are not typical, but vary considerably. The newly-qualified practitioner finds a great difference between the cases he was taught on and those he encounters in practice. The author has bridged the gap and written a book based on cases and experiences from his own practice. No references are made to other writers; the book is the result of the author's own observations and treatment.

The major part of the book is devoted to gynaecological complaints. Particularly instructive are the chapters on gastro-intestinal complications of female ailments, and their prevention. Prescriptions are plentiful and will be of value to the practitioner, but throughout the book special stress is laid on the value of prevention.

There is much that is controversial in the book, an example being non-interference in severe puerperal infection of the uterus. This does not however detract from the value of the book, as a whole.

The book should prove of great value to practitioners interested in female ailments and will be read with advantage by specialists.

S. N. H.

THE RHEUMATIC DISEASES. A CONCISE MANUAL FOR THE PRACTITIONER.—By G. D. Kersley, M.A., M.D. (Cantab.), M.R.C.P. (Lond.). 1934. William Heinemann (Medical Books), Limited, London. Pp. xiii plus 88. Illustrated. Price, 6s.

THE part played by rheumatic diseases in causing loss of work and inefficiency is very important. So much has been written during recent years about this vast subject, that it is very difficult for the busy practitioner, whose time is limited, to keep pace with the literature. Dr. Kersley's book therefore is very welcome. The writer in his introduction says that he has endeavoured to include the maximum of useful and up-to-date information in the very minimum of space, and in this he has certainly succeeded. In the compass of less than a hundred pages he has described the clinical features of typical examples of the various forms of diseased conditions met with in this group. A sufficient account of the pathology has been given to enable the reader to appreciate what is taking place in the tissues of the patients, and the treatment has been discussed in detail. Various chapters of the book deal with rheumatic fever, rheumatoid arthritis, fibrositis (including lumbago, sciatica, brachial neuritis, etc.), osteo-arthritis, climacteric arthritis, spondylitis and gout. The chapter dealing with physiotherapy is very interesting and explains how the various treatments are to be carried out.

The book is very practical, is written in a lucid and concise manner and will be a very useful addition to the practitioners' series. The importance of the subject of arthritis is being appreciated in this country and this book will help to draw the attention of senior students and practitioners to the recent work on this subject.

R. N. C.

INTERNATIONAL CLINICS. Volumes I and II, Forty-fourth Series, 1934.—Edited by Louis Hamman, M.D. J. B. Lippincott Company, Philadelphia and London. Pp. iv plus 320 in volumes I and VIII plus 317 in volume II. Illustrated. Price, 50s. per set of four volumes. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 37-8

THE two volumes of *International Clinics* received contain clinical lectures and original articles dealing with the ætiology, pathology, diagnosis and treatment of important medical, surgical and obstetrical diseases together with the others pertaining to special and sub-branches of the subjects. The articles are all contributions from authorities on the various subjects dealt with and are lucid and well written. The information given is important and up to date; the bibliography at the end of the articles is very valuable and will be useful to the reader. Besides discourses on the many commoner diseases that are met with in everyday practice, the volumes also give résumés of recent advances in special branches of medicine, pediatrics, surgery and obstetrics. A few diseases dealt with in these volumes deserve special mention inasmuch as the information contained is of great practical value. Examples of these are hepatic insufficiency, the management of old age conditions and the sections on recent progress in medicine and surgery in volume I; the pathogenesis of anterior poliomyelitis, operative shock, collapse therapy in the treatment of pulmonary tuberculosis, the medical and surgical aspects of peptic ulcer and the sections on the recent progress in obstetrics and pediatrics in volume II. The volumes are well got up and contain excellent plates in addition to many ink sketches, and we strongly recommend them to the practitioner in this country.

R. N. C.

MELANCHOLIA IN EVERYDAY PRACTICE. CLINICAL TYPES, DIAGNOSIS, TREATMENT.—By Edwin L. Hopewell-Ash, M.D. (Lond.). 1934. John Bale, Sons and Danielsson Limited, London. Pp. 136. Price, 7s. 6d.

IN this small book the author has described some of the important clinical types of psychosis, usually classed as melancholias, and of manic-depressive psychosis, which are frequently encountered by general practitioners but not properly recognized. The first eight chapters deal with various clinical types of melancholia, their differential diagnosis from schizophrenia, paranoia, paranoid psychosis, etc. The book is full of comparative tables, charts and clinical histories to illustrate various phases of these ailments. It is written in simple and plain English and will serve as a refresher to students going up for examination and to young practitioners.

R. N. C.

MURRELL'S WHAT TO DO IN CASES OF POISONING. (Fourteenth Edition). By P. Hamill, M.D., D.Sc., F.R.C.P. 1934. H. K. Lewis and Company Limited, London. Pp. viii plus 208. Price, 5s.

THE book was first published in 1881 and the fact that this is the fourteenth edition is sufficient proof of the popularity and success of this volume dealing with the treatment of minor emergencies in everyday practice. The book opens with the definition of a poison and the classification of this group of drugs. The author then proceeds with the differential diagnosis of cases and instructions to the general practitioner as to how to send the specimens from cases of poisoning for examination to the chemical examiner for medico-legal purposes. The portions dealing with the requisites of an 'antidote case' which he considers should be in possession of every practitioner are a valuable addition in this volume. The wise advice regarding the charging of proper fees in these cases is interesting and should be noted by practitioners. The

main body of the book deals in a lucid and concise manner with the individual poisons, mode of their ingestion, their fatal doses and indications for treatment. As cases of poisoning are exceedingly common in general practice, the reviewer can confidently recommend this volume to advanced students and practitioners for ready reference.

R. N. C.

A TEXTBOOK OF HISTOLOGY: FUNCTIONAL SIGNIFICANCE OF CELLS AND INTERCELLULAR SUBSTANCES.—By C. V. Cowdry. 1934. Henry Kimpton, London. Pp. 503. Illustrated. Price, 25s.

THERE are now many books on histology available to the student and the justification for yet another one seemed to the reviewer to be very doubtful, but a natural antipathy to a new-comer was at first mitigated when he read the name of the author and then rapidly overcome—not by a formal apologia in the preface, but by the book itself.

The author points out that in books of histology there is a tendency to supply a large number of illustrations of histological structures that the student will see for himself in actual sections, whereas the main object of the illustrations should be to make him understand the meaning of what he sees; that is to say, the book should not attempt to replace the practical class by giving photographs of all the sections that the student is likely to see, but should supplement the teaching of these classes by explaining what he does not and cannot see in sections. Another feature of the book is that it introduces a little more physiology than does the usual histology textbook; this helps the student to look upon the cell, not simply as a cell with a certain characteristic structure, rather as a single unit with a special function but dependent on its surroundings and only acting as an integral part of a greater whole with the rest of the cells of the body.

The book is written quite definitely for the medical student and for this reason we looked forward to finding dogmatic statements regarding certain controversial points, e.g., on the origin of the monocyte, as suitable subjects for criticism, but we were out-manoeuvred, as the author gave a very good account of the different theories but refused to commit himself. In fact he took a somewhat cynical view of the controversy into which the unitarian, dualist, and trialist have entered 'with the fervour of a missionary campaign', and which he suggests has led, as has the bacteriophage controversy in this country, to threats of legal action. In the sections on blood formation, the blood cells and blood destruction all recent work has been taken into account and he gives a very fair presentation of the subject. His chapter on the spleen is a short one, but in it he gives a clear account of the structure and functions of this organ, as far as our present knowledge goes; his description of the spleen as 'a great blood filter and the headquarters of the reticulo-endothelial system' is perhaps not an entirely comprehensive one, but as complete a description as one can hope to give in a single line, and is worth remembering.

A list of references is included; this will be useful to more readers than the undergraduate student. We imagine that some of his remarks, e.g., 'whose paper should be read by every medical student', will tend to alarm the average student, who probably thinks that if he masters the contents of the textbook he will have done about as much as can be expected of him, as far as satisfying his examiners is concerned, but some have higher ideals.

The quality of the paper, print and binding are of a very high order, and there are a large number of very excellent coloured plates. It is a book that we can strongly recommend to both the student and his teachers.

L. E. N.

MATERIA MEDICA FOR NURSES.—By A. Muir Crawford, M.D., F.R.F.P.S.G. Third Edition. 1934. H. K. Lewis and Company, Limited, London. Pp. viii plus 100. Price, 3s. 6d.

IN preparing this edition, every care is taken to bring the book up to date. The principal changes in the new edition are in the chapters dealing with the commonly used drugs and the interpretation of the prescriptions. The book is concise and clearly written and supplies all the information regarding the elements of materia medica and pharmacology of drugs that are necessary for the nurse to know. We have no doubt that the present edition will maintain the popularity which the preceding editions have enjoyed.

R. N. C.

MATERIA MEDICA FOR NURSES.—By L. Oakes, S.R.N., D.N., and Arnold Bennett, M.P.S. 1934. E. and S. Livingstone, Edinburgh. Pp. viii plus 339. Available from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 3-12

IN preparing this edition every care has been taken to bring the book up to date, and several new drugs have been added from the *British Pharmaceutical Codex*. The book presents in a lucid and concise manner the essential details of composition and dosage of the common official and non-official drugs and preparations, together with short notes on their pharmacological action. The arrangement is clear and methodical and the doses are given in both the English and the metric systems. The chapter on poisons and antidotes, and the appendix containing examples of methods of calculating doses and percentage solutions are very helpful. In fact, this small book presents a short summary of the elements of materia medica and includes sufficient material to enable the nurse to acquire knowledge of the subject in accordance with the requirements of the General Nursing Council. It will be very helpful to the members of the nursing profession, not only for examination purposes but also as a handy book of reference. The printing and finish of the book maintain the publishers' high standard.

R. N. C.

ANÆSTHESIA AND ANALGESIA IN LABOUR.—By K. G. Lloyds-Williams, M.D., B.S. (Lond.). 1934. Edward Arnold and Company, London. Pp. 96. Illustrated. Price, 5s.

THE author has carefully dealt with the matter in a very easy and impressive style. The subject is discussed under various headings according to the different methods of analgesia used in different stages of normal and abnormal labours: 'Twilight sleep' (morphine-hyoscine narcosis) has been described in detail. The initial dose is morphine $\frac{1}{4}$ grain and hyoscine $\frac{1}{150}$ grain; the hyoscine is repeated at hourly intervals in doses of $\frac{1}{450}$ grain. Complete loss of memory indicates full narcosis. Gwathmey's quinine-oil-ether method is much in vogue in New York; a $\frac{1}{4}$ grain of morphine is given hypodermically with an intramuscular injection of 2 c.cm. of 50 per cent magnesium sulphate which prolongs and increases its effect very appreciably. This is supplemented by a rectal injection of a mixture containing:—

Quinine	..	20 grains
Alcohol	..	40 minims
Ether	..	2½ ounces
Olive oil	..	4 ounces

The result aimed at is analgesia, not anæsthesia.

In the second stage, gas and oxygen is the anæsthetic of choice, where this is available. A usual mixture is 80 per cent nitrous oxide and 20 per cent oxygen.

For Cæsarean section, spinal anæsthesia has been recommended as the best; percaine (1:1500 in 0.5 per cent saline) is the drug advocated. Headache is less likely to occur if a fine needle is used. In severe cases, 6 ounces of magnesium sulphate, given four-hourly

as an enema, is of service. Intravenous glucose or 2 c.cm. of 50 per cent magnesium sulphate intramuscularly is said to give relief. Vomiting is partially dependent on the fall of blood pressure: ephedrine 1½ grains or pituitrin 1 c.cm. is indicated. No excessive fluid should be taken; solids or semi-solids may be given.

For toxæmia cases, sedative drugs, e.g., potassium bromide, chloral hydrate and opium, may be given in the early stages. Rectal administration of ether or paraldehyde is not contra-indicated. In the second stage, gas and oxygen should be given with ether. For cardiac diseases, chloroform should be avoided in failure of compensation. In pulmonary congestion, ether is to be avoided. Gas with increased quantity of oxygen is advocated; in the early stages, morphine ½ grain with atropine 1/100 grain is very good.

There are several illustrations of gas-and-oxygen apparatus, both for hospital and private use. It is really a valuable book with practical details and should be read by those interested in obstetrics and general anaesthesia.

P. K. M.

MAN AND WOMAN. A STUDY OF SECONDARY AND TERTIARY SEXUAL CHARACTERS.—By Havelock Ellis. Eighth Edition. Revised. 1934. William Heinemann (Medical Books) Limited, London. Pp. vii plus 469. Illustrated. Price, 10s. 6d.

THE great advances of recent years in biological knowledge have led the indefatigable writer of this book to revise and remould it for the seventh time, so as to bring it up to date and at the same time make it more suitable for the general reader.

The physiological, anatomical and psychological characters of the human race are taken *seriatim* and their differences in man and in woman fully considered. It is found from this survey that man excels in some respects and woman in others, so that through the gradual stages of evolution an almost perfect compensatory balance between the sexes has been established.

The book gives a carefully-reasoned discussion on the subject of the capability of women to replace men fully in modern life, and while the author shows that the partial emancipation of women from home duties has been of benefit, her entire freedom from care of the home and rearing of children is biologically unsound and cannot be successful in the long run, and it is wrong to look on this inability of women completely to replace men in industrial and business life as evidence of inferiority.

It is a book that all thinking persons might read with advantage and should be carefully studied by the extremists of both sides who claim either absolute equality of the sexes or absolute superiority of one sex over the other, for to this class it will convey a lesson of moderation and a realization that the undoubted differences between man and woman are not indications of the superiority or inferiority of either, but are truly complementary to each other, and are differences which have gradually evolved throughout the ages, are necessary for the continued progress of the human race, and cannot be upset at a moment's notice.

P. A. M.

A PRACTICAL BOOK ON BIRTH CONTROL.—By K. V. Mathew. Third Edition. 1934. Published by Mrs. A. Mathew, Travancore, S. India. Pp. 254. Illustrated. Price, Rs. 2-4

DR. MATHEW's small book 'Birth Control' adds yet another to the long list of so-called practical books on birth control methods. There are nowadays so many good and cheap books on the subject in English that one feels the author's energy and time would have been better spent in preparing a vernacular

edition. His intention is to bring birth control within the reach of a 'few of the neediest of his fellow beings' and English is hardly the medium of choice for such a purpose. However, a third edition of the book has been called for since June 1933, and it is therefore meeting a demand.

Dr. Mathew is writing for the layman, consequently a discussion of the methods of procuring abortion seems rather out of place. The same applies to much of the anatomical detail of the external sex organs. It is quite unnecessary for a sound understanding of the mechanism of the methods described and could be omitted without detriment.

The get-up of the book is poor, the English lacks style, and the proof reading has been very badly done. On the other hand the latest methods of conception control, even those still in the early experimental stage, are mentioned.

J. M. O.

RADIOLOGICAL TERMINOLOGY.—By C. E. Gaitskell, M.R.C.S., L.R.C.P. (Lond.). 1935. J. and A. Churchill Limited, London. Pp. 90. Price, 5s.

IT is a continual matter of regret to us that no English publisher brings out a purely English medical dictionary. American medical dictionaries abound and these have gone a long way to meet the needs in this direction of Great Britain and her colonies, for the best amongst these American dictionaries are Anglicized, or semi-Anglicized; that is to say, if you look up 'haemorrhage' you will find half a column of words commencing with the syllable *ham*, but for the rest you are politely requested to 'see *hem*'; there you will find 17 columns of words spelt with an *e* where English writers would use the diphthong *æ*. The result is that you cannot 'trust' American medical dictionaries, and you may sometimes be lured into using an Americanized spelling, or if you are a die-hard, of going to the other extreme and using a pedantic one.

The book under review has the special virtue of being completely English. It however deals only with one special subject, as its title suggests. Nor is it strictly a dictionary, though it serves the functions of one within its limited scope. It will be a useful guide to the practitioner who finds it difficult to read diagrams and quite as often impossible to understand and appreciate the full significance of the radiologist's report. It should also prove useful to students, nurses, and apprentice technicians in radiographical departments.

ILLUSTRATIONS OF REGIONAL ANATOMY.—By E. B. Jamieson, M.D. Sections I to V. Section I:—Central Nervous System. (Contains 48 plates.) Section II:—Head and Neck. (Contains 61 plates.) Section III:—Abdomen. (Contains 37 plates.) Section IV:—Pelvis. (Contains 30 plates) and Section V:—Thorax. (Contains 27 plates.) 1934. E. and S. Livingstone, Edinburgh. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price—Complete set, Rs. 22-8; Separately:—Sections 1, Rs. 5-4; II, Rs. 7-8; III, Rs. 4-2; IV, Rs. 2-10; V, Rs. 3

WE do not feel that we are rating these books too high when we say that they are what anatomy students of a number of generations have been waiting for. Dr. E. B. Jamieson is a lecturer in anatomy and he knows how popular good drawings are amongst his students. Illustrations, however good, cannot completely displace the written or spoken word in the teaching of anatomy, but they can go a very long way towards doing this, and without good illustrations the lecturer will soon find himself addressing a gathering of cross-word-puzzle players. Dr. Jamieson has therefore decided to issue these illustrations in the form of loose-leaf books, so that his students may

carry away from his lectures more than a visual impression of his blackboard drawings; the loose-leaf form was chosen so that each illustration can be detached from its cover and pasted into the student's note-book.

The illustrations are coloured, and in our opinion quite adequately coloured, though the author states that in the originals from which they were prepared colour was used more freely. We cannot help feeling that the colouring of anatomical diagrams can be overdone; in no case has the lack of colour in these illustrations detracted from their clarity. Each section is very complete and we have failed to think of any naked-eye anatomical structure that has not been illustrated at least once, and usually in all its aspects.

The plates, which number just over 200, are divided into five sections, the central nervous system, the head and neck, the abdomen, the pelvis, and the thorax; the illustrations referring to each region are bound in a separate loose-leaf binding. The method of holding the leaves together is the simplest and most effective that we have seen, and we are surprised that this system is not adopted more frequently.

These illustrations should prove extremely useful to the teacher of anatomy in India, as well as to the student; they are very suitable for use in the epidiascope, or, where one is not available, to pin on to the blackboard as an aid to memory while a larger drawing is being made. The price is very moderate and many students will be able to purchase copies for themselves, but in this country it is to the teacher of anatomy that they will appeal particularly.

THE HUMAN GYROSCOPE: A CONSIDERATION OF THE GYROSCOPIC ROTATION OF EARTH AS MECHANISM OF THE EVOLUTION OF TERRESTRIAL LIVING FORMS.—By A. Kenealy, L.R.C.P. (Dublin). 1934. John Bale, Sons and Danielsson, Limited, London. Pp. 313. Illustrated. Price, 12s. 6d.

In presenting the consideration that, as plastic clay on the rotating disc of a little potter's wheel of industry is shapen and moulded in varieties of symmetrical three-dimensional forms, increasingly uprising in the vertical, so upon the rotating surface of the great terrestrial potter's wheel of creative evolution, the plastic matter of terrestrial organisms has been shapen and moulded in the countless diversities of increasingly complex, structurally differentiated three-dimensional forms of living species, progressively uprising in the vertical in the terms of increasingly complex elevated posture—I have ventured to base my argument upon the gravitation of the great Newton, instead of on the later Einstein theory.

To any reader who wishes to follow this argument through three hundred pages of metaphysical discussion, we can recommend this book. Its format leaves nothing to be desired, the type is large and clear and there are a variety of illustrations of such diverse subjects as the potter at his wheel, the giraffe in the Zoo, and pine trees in their natural surroundings: the connecting link is provided in the text, which, if somewhat abstruse, is written in commendable English, so rare in books that it is usually our fate to read.

HEART DISEASE IN THE TROPICS.—By H. O. Gunewardene, M.B., B.S. (Lond.), D.M.R.E. (Cantab.). 1935. Published by Messrs. Butterworth and Company (India), Limited, Calcutta. Pp. x plus 101. Illustrated. Price, Rs. 5

The writer in his preface says that he does not intend to give a description of the various diseases of the heart met with in the tropics, as these are dealt with very comprehensively in the works of many well-known men. The intention of the author is to deal briefly with the influence of the tropics on the incidence, course and prognosis of heart diseases and the

modifications required in treatment on account of the climate. He emphasizes the deleterious effects of ankylostomiasis on the cardiovascular system and refers to the part played by such diseases as beri-beri, blackwater fever, cholera, heat-stroke, leprosy, malaria, plague, trypanosomiasis, typhus, yellow fever, and diabetes, and gives illustrative cases in many instances. Chapters are also devoted to high blood pressure and therapeutic considerations of cardiac tonic drugs. The author has referred to his own experience in dealing with such cases, but on the whole the book is of too elementary a character to be of much use to practitioners in this country.

R. N. C.

THE STUDENTS' POCKET PRESCRIBER AND GUIDE TO PRESCRIPTION WRITING.—By David M. Macdonald, M.D., D.P.H., F.R.C.P.E. Tenth Edition. 1934. E. and S. Livingstone, Edinburgh. Pp. 263. Available from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 2-4

This useful little 'prescriber' has now reached its tenth edition and fifteenth reprinting. The history of the publication tells a story of decreasing intervals between reprintings. A new edition, rather than a reprinting, was necessitated in this case by the publication of the new British Pharmacopœia. Opportunity has been taken to make other alterations and improvements, and to bring the 'prescriber' up to date.

The introduction contains most valuable advice in prescribing. 'The tendency to use abbreviated terms in prescribing is much to be deplored' is a piece of badly needed advice. If this practice is to be deplored in a prescription, it is certainly inexcusable on the printed page, and we see that throughout this book, except that the legitimate abbreviations 'tinct', 'ol' and 'ung' are used, the prescriptions are given in full. Another feature is that the equivalent metric dosages are given in each case; in this edition the abbreviation 'mil' has been substituted for 'c.c.'.

The author, with the help of his publishers, seems to have compressed most of the information that one finds in the larger compendia into this vest-pocket volume. We can thoroughly recommend it to practitioners and students alike.

THE NATURE OF DISEASE JOURNAL. Volume III.—By J. E. R. McDonagh, F.R.C.S. Published by Messrs. William Heinemann (Medical Books) Limited, London. Price, 10s. 6d.

As this book presented few of the characteristics that he had been in the habit of associating with the word 'journal', the reviewer looked the word up in the *Shorter Oxford English Dictionary*. Amongst a number of meanings he found 'a record of travel', 'a daily record of events or occurrences kept by any one for his own use', and much further down the column 'any periodical publication containing news in any particular sphere'. The use of the word in this case is thus justified.

The 'journal' is edited and apparently contributed in its entirety by Mr. J. E. R. McDonagh, F.R.C.S. This editor-contributor has very unusual ideas on the origin and nature of disease, and anything that he writes, one may be certain, will be stimulating. The contributions in this publication are no exception.

The reviewer found it difficult to grasp the exact significance of his theories and he finds it quite impossible to convey these to others in the few words that are permitted in a review. Perhaps the quotation of the first few lines of the 'editorial' will help:—

'From the work the author has done to date, and the assistance he has been able to derive from the discoveries made by the modern astronomers, it has become possible, by arguing from the particular to

the general, to throw some light upon the origin and nature of disease. The work upon the blood in health and disease, and the action of drugs upon the protein particles in the plasma, support the view that the universe in an early stage in its career was a limitless elongated oval homogeneously filled with some primitive material'.

For the rest, the subjects on which he has written, are rheumatism, diseases of women, 'infection from within', and 'infections from without'. Chronic intestinal intoxication appears to be the author's long suit; this is the root-cause of all ills and specific micro-organismal infections are only secondary.

He states that the common cold and influenza can in every case be aborted by the use of 'anepidem', a preparation made at the Nature of Disease Institute, Limited. If this claim can be established, Mr. McDonagh is certainly a world-benefactor.

The 'journal' is published in the form of an attractive book with good cloth binding. The contents will be found very stimulating.

Abstracts from Reports

HONG KONG MEDICAL AND SANITARY REPORT FOR THE YEAR 1933 BY A. R. WELLINGTON, DIRECTOR OF MEDICAL AND SANITARY SERVICES

In the absence of some system of registration of sickness the only sources of information available are the death returns, the returns of notifiable diseases, and the figures furnished by the Government hospitals and the western clinics of the Chinese hospitals. The number of deaths recorded indicates very correctly the deaths which have taken place in the colony but the figures regarding general diseases are only a fraction of the whole and too much importance should not be placed on deductions made from them. Though the educated Chinese appreciate the value of Western medicine the bulk of the population still pin their faith to the old-fashioned Chinese decoctions and, when ill, seek advice from one or other of the many empiricists or herbalists who practise in the colony. A number of those who enter the Government hospitals do so only after they have made full trial of Chinese medicines and when their disease is well advanced.

Year by year, however, the value of Western medicine becomes more and more appreciated. Proof of this is the ever-increasing number who attend the outpatient departments of Government hospitals or seek admission to the wards. Another proof is the success of the infant welfare clinic which was opened in Wanchai on 25th April, 1932, and which has become so popular that there is need of further accommodation.

Judging from the death returns the health of the colony was better than that of the previous year. The crude death rate was 22.38 per mille as compared with 25.02, the rate for 1932.

Malaria

This disease which in the early days of the colony was the great cause of death and from which Hong Kong derived its reputation of unhealthiness has now practically disappeared from the populous centres of Victoria and Kowloon as the result of the destruction of the breeding places of the carriers through efficient drainage. There is still some malaria in the outskirts of the two towns and a considerable amount in the rural areas of both the island and the mainland.

Investigations have proved that swamps, ponds and other collections of water in the open plains are more or less harmless and that the real danger lies within mosquito flight distance of the foot of hills and of valleys where collections of spring water in pockets, pools, swamps and streams form the breeding places of *Anopheles maculatus*, *Anopheles minimus* and *Anopheles jeyporiensis*.

Why it is so we do not know, but spring water which has not lost its sparkle does have an attraction for these three species. As a rule such water has a faint acid reaction due to dissolved carbonic acid gas. When it loses this and becomes flat it ceases to attract.

For many years the chief vector in the colony and new territories was believed to be *A. maculatus*. The researches of Dr. Jackson have proved this to be incorrect. *A. maculatus* is a carrier but is of far less importance in the spread of malaria than *A. minimus* and *A. jeyporiensis*.

It appears that species of mosquitoes, like races of men, can under different conditions of climate and surroundings develop differences in habits and tastes for food. *A. maculatus* in Malaya readily takes human blood and is a very potent agent in the spread of malaria. In Hong Kong, where it is very prevalent, it seems to prefer animals to humans and its importance as a vector of paludism is much less pronounced.

Though paddy swamps on the open plains are factors of little importance in the spread of malaria the same cannot be said of the irrigated terraces which form the rice fields of the hilly country. These have been shown by the Malaria Bureau to be, under certain conditions, prolific breeding places for that powerful carrier *A. jeyporiensis*. The irrigation ditches leading to and from the rice fields harbour both *A. jeyporiensis* and *A. minimus*.

Here as in Malaya disturbances of the soil often result in the formation of small collections of water which for reasons unknown attract the malaria mosquito and in which they deposit their eggs. The breaking of the soil is not a direct cause of malaria but a predisposing factor in a chain of events which favour the spread of the disease.

The most malarious areas are, therefore, those in or near the hills. Unless carefully watched and carefully controlled, works in the vicinity of the hills which involve disturbance of the soil such as roads, railways, or waterworks are nearly always attended by high sickness and death among the labour forces employed. In Malaya this was especially the case when the soil was of granite formation and the same applies in Hong Kong.

The total number of deaths attributed to malaria was 414, giving a death rate of 0.50 per mille for the colony. The lowness of the rate is, of course, due to the fact that the great majority of the population living in the drained urban areas are outside the zone of flight of malaria-carrying anophelines and, therefore, not subject to risks of attack.

Filariasis

Researches carried out by the malariologist show that a higher percentage of the people harbour micro-filaria in their blood than was formerly supposed.

Tuberculosis

Pulmonary tuberculosis ranks second to bronchopneumonia as the principal cause of death. The total number of deaths was 2,225, that for 1932 being 2,042. The death rate per mille was 2.71 as compared with 2.52 for the previous year. Pulmonary tuberculosis in the majority of cases is a disease which unfits the individual for the active exercise of employment months or even years before death supervenes. Because of the tendency of those unable to work and earn a living, to leave Hong Kong for their villages in China, the deaths reported form an incomplete index of the prevalence of the disease.

Leprosy

Though leprosy is a notifiable disease very few cases are notified. The number of lepers in the colony is not known but assuming that the incidence rate is the same as that of the neighbouring countries the total number cannot be less than 500 and it is probable that it is nearer 1,000. To many, these figures will appear to be exaggerations, nevertheless they are accepted by all who are authorities on the subject and have taken the trouble to make the necessary enquiries.

Plague

For the last four years no case of plague, human or rodent, has been reported in the colony. The disease has disappeared from Hong Kong and the same may be said of South China generally. The rat population is much the same as it was and so far as we know there is no change in quantity or quality in the flea population. The sanitary conditions in Hong Kong are generally better than they were but in the majority of Chinese towns there is little change. We must accept the fact that the rise and fall in plague figures have not been satisfactorily explained. We know that plague is primarily a disease of rats communicated to man through the rat flea, but we have to admit that we know little of the reason for the rise and fall in the incidence of disease among rodents.

Smallpox

Every year during the winter months this disease manifests itself in outbreaks which are sometimes epidemic and sometimes sporadic, to disappear with the advent of summer. During the year 566 cases were reported, of which 392 were notified through the medical officers in charge of mortuaries, that is after death had occurred. The total number of deaths was 433.

Cholera

No cases of cholera were reported during 1933.

REPORT ON THE PUBLIC HEALTH ADMINISTRATION OF BURMA FOR THE YEAR 1933. BY E. COTTER, MAJOR, I.M.S., OFFG. DIRECTOR OF PUBLIC HEALTH, BURMA

WHILE Burma records in 1933 the second lowest birth rate and the second lowest death rate, its infant mortality rate is at the other end of the scale and is exceeded only by the Punjab, the Central Provinces and Bengal.

In the rural areas the bulk of deaths are ascribed to fevers and 'all other causes'. It is not possible at present to obtain more accurate information of the causes of death, as in practically every case the diagnosis has to be made by a village headman, there being no medical practitioners in the village tracts. Undoubtedly, much of the fatal fever is to be ascribed to malaria. As for the large group of 'all other causes', it is impossible with our present statistics to attempt anything approaching an accurate analysis, but it is safe to say that infantile mortality constitutes a big proportion. In towns, the three leading

causes of death are respiratory diseases, infantile diseases and fevers. Of the fevers, 41 per cent are ascribed to malaria. The main proportion of the deaths due to 'all other causes' are ascribed to debility and anæmia, circulatory, urinary and digestive diseases.

The freedom of the province in the last four years from cholera and plague has been remarkable. Of these the change for the better is most marked in the case of cholera, which caused only 179 deaths in 1933 compared with an annual average for the last 20 years of 4,851. The 972 plague deaths in 1933 compare favourably with an annual average for the last 20 years of 4,826. Smallpox still prevails to an unsatisfactory extent and caused 1,506 deaths in 1933 compared to an average over the previous 20 years of 1,802.

Improvements in sanitation have been rendered very difficult in the last three years by the financial stringency which has paralysed the efforts of both Government and of local bodies; little has been possible in the way of improving such elementary services as water supplies and conservancy. It is true that up to now the general population has tolerated a very low standard of environmental sanitation without protest; but there are signs that this attitude is changing. Amongst the intelligentsia at any rate a growing sense of the importance of public health is apparent. The health education carried on in the schools for the last decade has not been without effect. Health lectures are becoming fashionable, and the high infantile mortality rate has caused an appreciable number of people to wonder and enquire what is wrong. An outbreak of epidemic disease is no longer regarded as an inevitable dispensation of providence.

In the increasing education on health problems lies one of the strongest weapons in the fight against preventable disease in Burma. It is from this class of people that the future local self-governing bodies will be largely drawn, and it is only when our municipal committees and rural councils are filled by those who recognize that one of their first duties is to guard the health of the people, that we are likely to get that much-needed improvement in environmental sanitation.

A word of praise is due to the provincial press which for the last few years has been generous in giving publicity to health matters, not alone by the publication of educative articles but in drawing attention to glaring instances of neglect on the part of local bodies to provide reasonable standards of sanitation.

In general it can be said that the public health in the province in 1933, when compared with previous years, was satisfactory. But there is a vast field for improvement. Much can be done without waiting for large sums of money to be made available. This is especially so in the case of infantile mortality, one of the root causes of which is ignorance on the part of the mothers.

Malaria.—Malaria continues to cause an extensive amount of sickness and mortality in certain of our rural areas. The expensive nature of permanent anti-mosquito measures, combined with the financial stringency, has made it impossible, except in a few places, to adopt anything more than palliative measures such as the issue of cinchona febrifuge tablets. In fact, the issue of cinchona febrifuge tablets has been the only practical step possible.

A serious outbreak, assuming epidemic proportions, occurred in Shwebo district in September in a group of villages 8 miles west of Shwebo town in the canal area. An investigation by the malariologist showed that the disease had been endemic in two villages before the infection spread. A special sub-assistant surgeon was placed on duty in the area, and an intensive distribution of cinchona febrifuge tablets was

carried out. Magwe district reported malaria outbreaks in Taungdwingyi and Myothit townships, where the malaria-carrying mosquitoes were reported to be breeding in the paddy cultivation. Special steps were taken here to revise the list of retail vendors of cinchona febrifuge tablets, and their number was increased with a view to making the tablets available in all these villages. Educative propaganda by distribution of pamphlets, magic lantern demonstrations and cinema shows was conducted to enlighten the people on the causation and prevention of the disease.

A spleen census taken in the Kengtung subdivision of the Southern Shan States showed that in some places the rates varied from 72 to 92 per cent. These rates give an idea of how intense malaria is in these areas.

Maternity work.—Maternity work in Burma is under the control of the medical department, and only when midwives are employed by child welfare societies does their work come within the scope of this report. There were 35 such midwives employed by 9 child welfare societies during the year; they conducted 5,682 confinements.

There are no trained *dais* in Burma. The training of *dais* or *wunswees* was attempted in 1929 and 1930 by the Society for the Promotion of Public Health, Maymyo, but, proving unsuccessful, was discontinued. Sub-section 2 of section 8 of the Burma Midwives and Nurses Act, which prohibits unqualified persons practising midwifery, has now been applied to the Maymyo municipal area and came into force in July 1933.

Child welfare work.—The growth of child welfare work in Burma is dependent on the supply of trained health visitors, and unfortunately the number of such workers available in the province at present is very small. The Burma branch of the Indian Red Cross Society has sent two candidates annually for health visitors' training to the Lady Reading Health School, Delhi, for the last five years, and, as a result, eight such health visitors are now employed in the province; but the demand and need for health visitors is far greater than can be supplied by sending girls as far as Delhi for training, and it is now recognized that a health school in Rangoon for the training of health visitors is an imperative and urgent necessity. For the last three years attempts have been made to organize such a school in Rangoon, but insurmountable difficulties led to its postponement. Things have now taken a turn for the better and the Central Maternity and Child Welfare Bureau of the Indian Red Cross Society has very generously promised a grant of Rs. 4,800 per annum for three years if such a school is started. The Burma branch of the Indian Red Cross Society, the Local Government and the Rangoon Corporation are co-operating, and it is confidently hoped that the school will be started in the early part of 1935. Not alone will such a school be able to provide us with an adequate number of health visitors, but it will also mean that the students are trained under conditions similar to those under which they will subsequently work. There should also be a larger selection of suitable candidates than is the case at present when it is necessary to go to Delhi for training.

School medical inspection.—The inspection scheme for the improvement of school hygiene and the systematic medical care of school children was introduced in 1922, and, each year after that up to the 31st March, 1932, a grant in aid was given by Government to each recognized Anglo-vernacular, English and normal school which adopted and worked the scheme. Each year an increasing number of reports were received from schools, showing that medical inspection was being gradually and effectively extended. In the year 1931 a total of 176 reports were received, and they gave a record of satisfactory work which must have had a beneficial effect on the health of the children.

In December 1931, with the collapse of the provincial finances and the need for urgent and stringent economy, Government decided to suspend the grant from April 1932. This step was regarded with misgiving by those concerned with the working of the scheme, but it was hoped that the suspension would be of short duration. This, unfortunately, has not proved to be the case and this is now the third year in which no financial help was given by Government for this very necessary work.

As was only to be expected, the number of annual reports of medical inspections received for 1932 showed a drop to 68, and the majority of those reports were from honorary medical officers, whose public spirit had induced them to carry on without pay the work in which they had been previously engaged. It would be unreasonable to expect this system of voluntary medical inspection to last, and for that reason the Director of Public Instruction in 1933, with Government's concurrence, proposed to the schools a scheme for making a four annas charge per mensem per pupil for medical attendance. Any hopes regarding this proposal of the Director of Public Instruction were dashed to the ground, by the almost unanimous opinion of the schools and inspectors that the parents, at the present time, cannot afford even four annas per mensem towards the cost of the medical care of their children.

To-day, therefore, the provision of medical inspection is left to the option of those Anglo-vernacular and English schools that find it possible either to provide the cost or that can still arrange for free medical inspection.

The most common defects noticed at the medical inspections were defective teeth 15.88 per cent, enlarged tonsils 11.17 per cent, defective vision 5.01 per cent, trachoma 3.93 per cent, anaemia 3.93 per cent and skin disease 3.03 per cent. A comparison of the percentages of defects in school children during 1933 with those of the previous five years reveals that there is a decreased incidence in most of the diseases. As, however, the schools which have been able to continue medical inspection are probably those with a bigger income and with a type of pupil drawn from the higher grades of society, the lesser incidence of preventable physical defects is to be expected.

It is encouraging to note that some of the school staff have taken a genuine interest in following up the recommendations of the medical officers.

ANNUAL REPORTS OF THE CHIEF ENGINEER, PUBLIC HEALTH DEPARTMENT, BENGAL, FOR THE YEARS 1932 AND 1933

As in the previous years the 24-Perganas District Board requested the department to arrange for the supply of filtered water at the annual Ganga Sagar Mela. A temporary water-supply plant, including a distribution system with cisterns on pedestals at suitable centres on the mela ground, was installed, and chlorinated water was supplied to the pilgrims. This temporary waterworks was very useful and prevented the spread of cholera and other water-borne diseases in endemic form.

In connection with the anti-malarial measures in the decadent areas of Bengal a scheme for contour survey of the area lying between the Hooghly and Damodar rivers in the districts of Hooghly, Howrah and Burdwan was sanctioned by Government, and arrangements were made to start the work.

The English Bazar water-supply scheme, the second scheme designed according to the 'decentralized storage' system, was completed during the year. Like the Asansol scheme, this is quite successful in checking waste of water without the assistance of meters. It is gratifying to see that local bodies are gradually

realizing the advantage of this system of water supply. In this connection the visit to Asansol of a deputation from the Sanitary Board, Bengal, may be mentioned. This took place on the 1st March, 1932, and the members of the deputation, besides examining the various sections of the waterworks, interviewed certain householders who have house-connections, and questioned them as to the suitability and convenience of the system. The general conclusion of the report of the deputation were as follows:—

'The committee were very favourably impressed with the system and consider that it meets successfully many of the most serious difficulties that have embarrassed water supplies in Bengal towns in the past, and that these advantages can be got without excessive cost either of installation or maintenance. They think it desirable that its advantages should be more widely known amongst municipalities generally'.

Correspondence

CURE OF FILARIASIS

To the Editor, THE INDIAN MEDICAL GAZETTE
 Sir,—A gentleman residing in the filarial district of Gonda and suffering from periodical attacks of filarial pain and swelling of the right hip was suddenly attacked with chyluria on the 31st July, 1933. He had had two courses of myosalvarsan for the lymphangitis. Still the attack of chyluria was of a pretty severe type; every time the urine was chyloric. Sometimes even coagulated lymph was thrown out in big lumps. Two injections of solu-salvarsan were given and later one full course of neostibosan (which caused a very severe general reaction); but the disease would not yield to any treatment.

After a duration of seven and a half months, and about six weeks after the stibosan treatment, the lymph in the urine suddenly began to diminish rapidly. On the 18th March, 1934, and on the third day it disappeared altogether. This happened along with an attack of the old lymphangitis and sciatica of the right side which passed off in two weeks. The gentleman has had no filarial symptoms since then.

I am very puzzled over this case; was the cure effected through the natural thrombosis of the lymphatics or what?—Yours, etc.,

M. ASLAM OMAR, L.M.P. (Agra).

GONDA.

[Note.—Filarial lymphangitis and chyluria recur at varying intervals. Cure in chyluria is believed to be due to the formation of a thrombus which blocks the rupture in the lymphatic vessel and brings about relief of symptoms. It would be interesting in this case to get full particulars of the number of attacks of lymphangitis he has had with the intervals between them, and to watch the patient some time longer.—EDITOR, I.M.G.]

Service Notes

APPOINTMENTS AND TRANSFERS

LIEUTENANT-COLONEL H. E. MURRAY is confirmed in the post of Surgeon Superintendent, Presidency General Hospital, Calcutta, with effect from the 1st December, 1933, *vice* Lieutenant-Colonel A. H. Proctor.

Lieutenant-Colonel D. H. Rai, M.C., Professor of Pharmacology and Therapeutics, King Edward Medical College, Lahore, is appointed to officiate as Inspector-General of Civil Hospitals, Punjab, *vice* Colonel Reinhold, granted leave.

Lieutenant-Colonel K. G. Gharpurey is appointed, on his return from leave on 13th March, 1935, to be Civil Surgeon, Ahmednagar.

Lieutenant-Colonel J. M. R. Hennessey, Civil Surgeon, Jubbulpore, is appointed to officiate as Inspector-General of Civil Hospitals, Central Provinces, with effect from the 9th May, 1935, *vice* Colonel N. M. Wilson, granted leave.

Major S. R. Prall and Major J. S. Galvin have been confirmed in the Bombay Cadre of the Indian Medical Service (Civil), with effect from the 26th June, 1932.

Major J. S. Galvin is appointed as Officiating Presidency Surgeon, Bombay, *vice* Lieutenant-Colonel A. N. Thomas, D.S.O., proceeding on leave.

To be Lieutenant (on probation)

Geoffery Richard Callander Palmer. 17th December, 1934.

LEAVE

Colonel C. H. Reinhold, M.C., Inspector-General of Civil Hospitals, Punjab, is granted leave on average pay for two months and 20 days combined with leave on half average pay for three months and 26 days with effect from the 8th April, 1935, or any subsequent date on which he may avail himself of it.

Colonel N. M. Wilson, O.B.E., Inspector-General of Civil Hospitals, Central Provinces, is granted leave on average pay for four months with effect from the 9th May, 1935.

PROMOTIONS

Captains to be Majors

G. M. Irvine and D. Kelly. Dated 1st February, 1935.

S. D. Gupta. Dated 7th February, 1935.

Lieutenant (on probn.) to be Captain (on probn.)

B. F. B. Russell. Dated 1st August, 1934.

RETIREMENTS

Lieutenant-Colonel W. A. Mearns. 15th November, 1934.

Lieutenant-Colonel J. Kirkwood. 11th December, 1934.

Notes

SIEMENS X-RAY SPHERE

WHATEVER may be the view regarding the question of large or small x-ray plant, it cannot be denied that there are many fields of application in which there is a distinct demand for the smallest types. There is no sense in purchasing a four-valve apparatus for dental radiographic work only, and it is impossible to install a large output plant in a patient's house, for temporary use, to x-ray a broken leg for example. If such small apparatus is really to fulfil its function, its efficiency should not be below a certain level, the weight and volume being at the same time kept as low as possible.

Anybody attempting the solution of this problem will at first be tempted to secure the smallness of apparatus at the expense of efficiency and safety.

Reliability of operation should, however, in no circumstances be less than with any standard apparatus.

In high voltage technique, the oil-insulated high-tension transformer continues to dominate the field, because actually no other method of insulation offers the same security.

Although it is possible to obtain transformers of lighter weight by dry insulation, Siemens have, for reasons of greater safety, adhered to oil insulation.

The output of 10 mA at 60kV of the Heliodont has been proved correct by many years of experience; thus, in developing the new apparatus, they had no Heliodont and the well-known Nanos with the new apparatus tubes of smaller grid effect are used, which give higher efficiency and hardness of radiation.

It is obvious that the complete x-ray installation (transformer and tube housing) will be smallest if these parts are sufficiently closely arranged to permit of the almost entire elimination of high voltage leads. This measure, however, is not enough in itself to give a sufficient reduction in weight, as the transformer of normal design is much too heavy. It was only a radically new design of high tension transformer which enabled us to realize our aim.

A transformer of normal design consists of a rectangular core with suitably large opening for the copper winding.

This had to be a starting point for improvement. The high tension winding is, in accordance with known methods, and in keeping with normal requirements of safety, so strongly insulated with paper strips that the whole surface of the winding may be in contact with earthed parts (obviously with the exception of the connecting leads). The centre of the secondary winding follows orthodox design in order to permit of

the measurement of the tube current by means of an earthed milliammeter.

The iron core, of entirely novel design, consists of a circular central portion passing through the middle of the copper coil, and simultaneously carrying the primary winding. The magnetic circuit of the remainder of the iron path is completed by U-shaped strips, which are superimposed in lap formation, and the ends of which abut square on the centre core. Proceeding from the outer circumference, where they are superimposed in lap formation, and cover almost the entire circumference of the winding, these strips are directed upwards, the nearer they approach the interior, until at the joints they run parallel to the axis of the central core.

This arrangement results in the dimensions of the transformer being but slightly increased by the iron. It is to be emphasized that with this design and in spite of its advantages, no projecting iron parts are required.

This form of iron core represents the minimum of mean length of the iron part, for no other form of iron core can be visualized which would result in a shorter mean length. From this it follows, on the one hand, that we have thus reached the minimum of core weight, and on the other hand the additional, and equally important, advantage is secured, that the outer dimensions of the transformer also represent a minimum, a very simple geometrical form, which can be encased without leaving free spaces, being attained at the same time.

In consequence, the quantity of oil required for saturating the insulation material of the high voltage winding is also reduced to a minimum. A third, if less important, advantage is secured by the shortening of the mean length of the iron part by the reduction

of the number of necessary ampere-turns, i.e., a reduction of the no-load current is obtained. It was

gathered does not seem to affect their potency, but, as a rule, the spring is regarded as the best season. The roots are cleaned and dried in the air.

Cultural experiments are being carried out in Germany and Austria, with a view to obtaining a small tap-root with as many lateral roots as possible; these are gathered every two or three years. In order to increase the value of the primula cultures, it has been suggested that the leaves should be used for a pharmaceutical or other purpose, because, when given in four times the dose, they have the same effect as the root-organs. Further, the pleasantly aromatic flowers of *Primula veris* can be used for the preparation of extracts.

Writing on the physiology and pharmacology of expectorants Dr. T. Gordonoff, of Bern, says:—

'Tussipept is a fortunate combination. It is an ammonium salt of primula-saponin, and I have frequently been able to convince myself of its value and activity'.

We have ourselves used Tussipept in a number of cases and have found it very useful as a relief-giving expectorant.

THE FURNISS CLAMP FOR INTESTINAL ANASTOMOSIS

With this instrument the technique of end-to-end, end-to-side, and side-to-side anastomosis of the intestine is greatly simplified; there is a consequent saving of much time during the crucial part of an operation, whilst it leaves the surgeon secure in the knowledge that there should be no subsequent intestinal leakage.

Closure of the blind end of a piece of severed gut can also be accomplished with ease, and for convenience the technique of this latter procedure will be described immediately after a brief description of the clamp itself.

Description of clamp.—An instrument in stainless steel, it is a bowel-crushing clamp, which will only crush and not cut nor tear the gut, and in which the fulcrum is at the tip of the blades. The handles can be locked together by means of a thumb screw, so that when in use it will act as a lever of the second degree and give an even grip throughout the whole length of its blades. The blades are of deep section, coarsely and transversely serrated on their approximating surfaces, whilst a longitudinal groove is cut down the centre of each serration. On the closure of the clamp, the serrations interdigitate to form a sinuous line, whilst the longitudinal grooves approximate so as to form a tunnel through which a pin may be inserted.

Technique employed.—It is recommended that the surgeon should make himself well acquainted with this in the post-mortem room before employing it in the operating theatre.

Clamp the gut in the blades of the forceps and lock the handles. Transfix the gut by inserting the pin down the tunnel formed by the two longitudinal grooves in the blades so that the walls of the gut will be held together. Do this whilst the gut is fairly loosely clamped by the blades; then tighten the clamp.

Remove the distal portion of the gut, preferably with a cautery; then remove the clamp. The walls of the cut end are now firmly closed and are held on the pin to the sharp end of which a guard is fixed. A sero-muscular continuous suture is now applied so as to invert the serrated cut edge. The pin is now removed, when the gut will be found to be effectively closed and, if necessary, can be doubly secured by further suturing. As an alternative to transfixing the gut with the pin, a needle with a catgut suture

attached can be used to transfix instead. On the clamp being removed, the suture is drawn right through and its two ends tightened and tied, when a final purse-string suture completes the closure.

End-to-end anastomosis.—The two loops of the gut (four walls) are clamped together, the pin inserted and the distal portions removed by the cautery. On removal of the clamp, all four walls will be found securely held by the pin, the point of which is protected. A sero-muscular continuous suture inverts the serrated edges, and is continued on the opposite side of the pin, whilst further interrupted sutures ensure greater safety. The pin is now removed and the lumen of the gut established by digitally intussuscepting the upper into the lower segment so as to break up the temporary union of the four intestinal walls.

End-to-side anastomosis.—The technique is similar to that of an end-to-end anastomosis with the exception that a wall of the larger gut is elevated by tissue forceps so as to form a fold which together with the loop of smaller gut is clamped in the forceps. The distal parts are then severed and the operation continued as described above.

Side-to-side anastomosis.—Here, from each loop, the wall is elevated and the two folds, thus formed, clamped together when a technique similar to that of an end-to-end anastomosis is followed.

This clamp is obtainable from the Medical Supply Association Limited, 167, Gray's Inn Road, London, W.C.1.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette'. Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

TREATMENT OF PSORIASIS

By D. PANJA, M.B. (Cal.)
and

P. A. MAPLESTONE, D.S.O., M.B., Ch.B., D.T.M.
(From the School of Tropical Medicine, Calcutta)

(Department of Dermatology, financed by the Indian
Research Fund Association)

THE cause of psoriasis is not yet known, and the treatment is very unsatisfactory, for although many forms of therapy bring about partial or total disappearance of the lesions, the tendency to relapse is in no way affected; so that permanent cure is rare. Many theories* as to the cause of the disease have been advanced and we have investigated several of these, the results of which are given below.

Toxin theory.—It is said that the lesions are produced by a circulating toxin originating from a septic focus situated somewhere in the body, most often in the intestines. On this account there are a number of vaccines on the market prepared from the intestinal flora; these are claimed as specifics for psoriasis. In a series of cases examined we took four to six samples of stool from each case and in some we found *Entamoeba histolytica* cysts, in some vegetative forms of the parasite and on culture found various non-lactose fermenters belonging to the Flexner and Salmonella groups of bacteria. Treatment with either emetine or autogenous vaccines of the bacilli gave good results in a few cases only, and after considerable experience with the above treatment we have come to the conclusion that intestinal sepsis is not the cause of psoriasis.

Parasitic theory.—The disease is a local infection of specific bacteria or fungi; but this has not been definitely proved. We tried cultures from the lesions in various media at different temperatures, both aerobically and anaerobically, but did not get uniform results; staphylococci, yeasts, aspergillus and various other organisms were obtained. It has also been suggested that the parasite may be a filter-passing virus and the following workers have treated several cases based on this theory. von Mihailovic (1929) treated a few cases with alcoholic extract from psoriatic scales with variable success. Campbell and Frost (1930) treated fifteen cases by intramuscular injections of a suspension of the patient's scales finely ground in alcohol; all patients responded to this form of treatment in varying degrees. In 1931 Toma treated three cases with scale suspension

with the addition of 0.25 per cent formalin. Campbell and Frost (1932) published a further record of fifty cases treated with alcoholized scale suspension. They claimed that there was no reaction after the injections. Wrong (1933) treated ten cases by Toma's method; five out of the ten definitely improved, one of them being entirely cured.

We at first followed the technique of these workers using injections of alcoholized and formalized scale suspensions. The alcoholic suspension caused a good deal of burning pain at the site of injection and hence patients did not submit to it readily. The formalized saline suspension also caused pain and marked necrosis as well at the site of injection. In spite of these objections we persisted in treating five cases; but it was found that a large number of injections were necessary, and an adequate supply of scales was not available. Owing to these drawbacks we decided to cut out a piece of tissue from psoriasis lesions and make an emulsion of it for injection. Our idea was that the parasite, if it is a filtrable virus, will be found not only in the scales but also deeper down in the dermis. This probability is supported by the fact that the epidermal changes have been shown to follow changes in the dermis such as dilatation of vessels, elongation of the papillae, etc. These pathological findings suggested that the filtrable virus might be present in the corium in a more virulent state than in the more or less dry epidermal scales. The following technique was accordingly adopted.

An acute or a subacute early patch is selected and dabbed with rectified spirit, then a small piece of the diseased skin to the depth of the corium is snipped off with a pair of sterile curved scissors. The piece is weighed and mixed with pumice-stone dust and crushed in a sterile mortar until a uniform paste is produced. A few drops of normal saline may be necessary to make a good paste. The paste is then mixed with a measured quantity of sterile normal saline to make up the suspension to the strength of 10 mgm. in 1 c.cm. It is then filtered through a Keiselghur filter and the filtrate thus obtained is filtered again through sterilized Pasteur-Chamberland L3 candles, and 0.05 per cent phenol is added to the final filtrate. The initial dose was 0.1 c.cm. and it was injected intradermally. The injections were repeated every third or fourth day, increasing the dose each time by 0.1 or 0.2 c.cm., up to 1 c.cm. When the dose reaches 0.5 c.cm., subcutaneous injection is better as by this means the pain of intradermal infiltration is avoided. A course of ten to twelve injections was given as a rule and if necessary this was repeated after a fortnight; but only in a very few cases was a second course necessary. There was no reaction nor pain following these injections.

*The trophoneurosis theory has been long ago abandoned, so we have not studied it and there is a new therapy, advanced by Gruetz (1934), which we have not yet had time to investigate.

Twenty-eight cases were treated by the above method, the detailed results of which can be seen in the table. Four were quite cured; eight were nearly cured, a few minute spots only being left; two cases were apparently cured but

(3) This has been found less painful than the formalized or alcoholic filtrates recommended by other workers.

(4) A record of treatment of 28 cases by this method is given.

TABLE

Number	Caste and sex	Age in years	Duration of disease in years	History of relapses	Number of injections	Total amount in grammes	Result	REMARKS
1	M., M.	30	3	Every winter	12	1	Cured	No relapse this season.
2	H., M.	45	12	Worse every rainy season.	9	1	Nearly cured	No relapse for 10 months.
3	H., M.	25	7	Worse every rainy season.	6	0.85	Cured	Milder relapse in the beginning of winter and responded to treatment.
4	M., M.	45	4	Every winter	6	0.6	Cured	No relapse for 10 months.
5	H., M.	23	3	Every summer	7	0.9	Cured	No relapse for 12 months.
6	H., M.	16	3	Every summer	10	1.2	Cured	No relapse for 8 months.
7	H., M.	35	10	Every summer	12	1.5	Cured	No relapse for 1 year.
8	H., M.	17	4	Every winter	12	1	Cured	Lost sight of.
9	H., M.	35	12	Every rainy season.	10	1.1	Cured	No relapse for 16 months.
10	H., M.	45	5	Throughout the year.	7	0.14	Cured	After 1 gramme in 5 injections severe reaction. Treatment stopped for 14 days and 2 further injections of 0.02 gramme each, resulted in cure.
11	H., M.	..	14	Rainy season to winter.	10	0.1	Three-quarters cured.	Lost sight of.
12	M., M.	..	16	More or less all the time.	2	0.2	Disease flared up.	Patient has come again after 10 months and is being treated again.
13	H., M.	30	9	Every winter	10	0.8	Nearly cured	No relapse for 10 months.
14	E., M.	25	8	Irregular	8	0.8	No effect	Lost sight of.
15	H., M.	31	7	Irregular	12	1.1	Cured	No relapse for 16 months.
16	H., F.	14	8	Every rainy season.	8	0.6	No effect	Lost sight of.
17	H., M.	31	4	Every rainy season.	10	0.7	Cured	Lost sight of.
18	H., M.	37	1	Every rainy season.	6	0.5	Nearly cured	No relapse for 6 months.
19	H., M.	40	25	Irregular	10	0.9	Nearly cured	No relapse for 12 months.
20	H., M.	40	16	Always present	12	0.4	Cured	No relapse for 5 months.
21	M., M.	22	3	..	5	0.01	Cured	No relapse for 6 months.
22	H., M.	42	3	..	6	0.08	Nearly cured	No relapse for 11 months.
23	M., M.	30	2	..	14	1.2	Cured	No relapse for 13 months.
24	M., M.	40	10	Rainy season	10	0.8	Cured	Relapse after 2 months.
25	E., F.	24	5	Irregular	9	0.9	No effect	..
26	H., M.	31	2½	..	9	0.6	Nearly cured	Has not become worse again.
27	M., M.	40	10	Every winter	8	0.4	Nearly cured	Relapse after 6 weeks.
28	M., M.	45	12	Every winter	7	0.4	Nearly cured	No relapse after 14 months.

H. M.=Hindu male. H. F.=Hindu female. M. M.=Mohammedan male. E. M.=European male. E. F.=European female

relapses took place after three months and they are now improving on another course of injections; three cases did not respond to treatment and one flared up after two injections. We got equally good results with an autogenous filtrate or one from some other patient.

Summary and conclusions

(1) Our investigations have led us to believe that the toxin theory and the theories of bacterial or fungus infection as the cause of psoriasis are not correct.

(2) A new method of making filtrates of material from the lesions of psoriasis for treatment of the disease is described.

(5) The results are so favourable that the theory of a filtrable virus being the cause of psoriasis appears to be well founded.

SPLENECTOMY FOR TROPICAL SPLENOMEGALY

By A. N. PALIT, F.R.C.S. (Ed.)

LIEUTENANT-COLONEL, I.M.S.

Superintendent, Orissa Medical School and Civil Surgeon, Cuttack

Of all the various organs of the body even to-day the spleen deserves the name of the organ of mystery: it has been so described during the ages. It has no duct, no definite or peculiar secretion or function of its own, and, although it is affected seriously in many infections and in certain blood diseases, its removal seems to result in no permanent changes in the physiology of the body. Many persons on whom splenectomy had been performed remained in apparently excellent health for many years. Splenectomized women have passed through normal pregnancies, though miscarriage has been known to occur. Even in the young, splenectomy has a negligible influence on growth. Congenital absence of the spleen also seems to be compatible with health and life; at least two such cases are on record; one patient died of obstruction of the common bile duct at the age of 32, and the other of pulmonary tuberculosis at 45. Microsplenia has also been observed in some cases, a woman with a 21-gramme spleen lived to be 73. Even in disease the influence of the spleen is not easily distinguishable.

For certain pathological conditions which may or may not come under the vague nomenclature of 'tropical splenomegaly' it has been universally agreed that the spleen should be removed. The reasons for so strongly recommending such a serious operation are many:—

(1) Mechanical—the ill effects of having to carry about a huge functionless diseased organ inside the abdominal cavity can easily be guessed. Pressure and dragging on the different important organs must be concomitant with such enlargement. Removal of the spleen without any further treatment in case of malarial enlargement is followed by rapid improvement in general health.

(2) Danger of rupture is ever present, either spontaneous or more often as the result of even a slight blow or fall.

(3) Rapid return to health after splenectomy in certain blood diseases, such as splenic anæmia.

(4) The liver, which is enlarged in almost every case of splenomegaly, diminishes in size after splenectomy. The improvement is no doubt partly due to mechanical causes. The portal circulation is relieved and the amount of blood that the liver has to deal with is perhaps cut down by half or even more. (In health the normal spleen supplies one-seventh of the blood which goes into the portal vein.)

(5) Splenectomy is the only treatment which offers any measure of success in certain conditions.

Contra-indications to operation:—

1. Ascites.
2. Marked enlargement of superficial abdominal veins indicating advanced hepatic cirrhosis. These cases can only be regarded as grave surgical risks and will most probably die of hæmorrhage.
3. A fixed and immovable spleen.
4. Jaundice, unless the condition improves under medical treatment it would perhaps be very unsafe to operate.
5. Hodgkin's disease and Gaucher's disease.
6. Leukæmia. Splenectomy may be done after reducing the size of the spleen by radium. The operation will prolong life but will not cure the disease. Giffin states that the operation may be done in the very chronic form of the disease only, with a very fibrous spleen and a not very high white cell count.

It seems rather a pity that splenectomy has not been practised more often in India, though in Egypt it is a fairly common operation. I hope my experience, limited as it is, will be of some value.

Summary of cases

Results:—

Number of cases operated on	..	10
Recovered	..	9
Died of hæmorrhage from separated adhesions	..	1
Known to be well one to two years after operation	..	3
Known to be well up to six months after operation	..	5

Of the 9 who recovered, 8 were discharged from hospital in good health; one went away before he had regained his health, having developed broncho-pneumonia, then hepatitis and malaria. Benign tertian parasites were found in his blood. He was still debilitated when he left hospital but otherwise well.

Age and sex of patients.—One patient was 15 years old and one 16, five were between 20 and 35, two were 40 and one 45; only two of the patients were females (aged 16 and 40), and the patient who died was a man 40 years of age.

Malaria.—All gave previous history of fever, which is only to be expected, and six gave a definite history of rigors and intermittent attacks of fever. Two showed a benign tertian infection.

Ankylostoma infection.—All were infected with hookworms, some heavily. Most of them required two or three courses of treatment to eradicate the infection. This fact is interesting, because it is possible that ankylostomiasis plus malaria is the cause of many of

these splenomegalies, that are not due to kala-azar.

Kala-azar.—None of the patients were suffering from kala-azar.

Splenic anæmia.—Two, and perhaps three, were suffering from this disease. The red corpuscles were below 3 millions and leucocytes about 5,000 per c.mm. The liver showed cirrhosis, and adhesions were dense. Two of them gave a definite history of hæmorrhage from the bowel; one was doubtful. One, the girl of 16, had melæna and petechial hæmorrhages under the skin after operation; this was one of the patients that died subsequently.

Liver.—All showed enlargement of the liver from two to six fingers below the costal arch. Two showed a distinctly hobnailed appearance though very slightly. In two others the surface of the liver was reticulated. The liver was reduced in size in every case after operation.

Jaundice.—Eight had jaundice.

Ascites.—None had clinical ascites, though during the operation a little fluid was seen in some cases.

Duration of splenic enlargement.—Two gave a history of splenic enlargement for eight years, one each for seven and six years and two each for five, four and three years.

Size of spleen.—On admission the spleen in every case was much bigger than at the time of operation. In most cases it extended well over the middle line and below the umbilicus. In two cases it practically filled the whole abdomen. In one the swelling was cystic (this case will be given in detail). In the boy aged 15 even one finger could not be introduced between this organ and the symphysis pubis. The average weight of the spleens after removal was 4 pounds; the two biggest weighed 5 pounds 12 ounces and 5 pounds 6 ounces; and the smallest 2 pounds 12 ounces.

Blood.—Red cells varied from 2,700,000 to 3,700,000 per c.mm. before operation, but showed considerable improvement some time after operation. The improvement was gradual and maintained. White cells were 3,000 to 5,000 before, and went up to 6,000 to 11,000 per c.mm. after operation. Lymphocytes varied from 24 to 35 per cent and polymorphonuclears from 50 to 75 per cent; there was either a slight increase or decrease after the operation. Hæmoglobin was about 55 to 65 per cent and colour index was about 0.5 to 0.6. The latter showed steady and gradual improvement after operation.

Treatment.—Every patient was first admitted to the medical wards where a clinical examination and routine tests were done. If malaria was diagnosed or suspected, a thorough course of quinine and atebrin or quinine alone was given. Ankylostomiasis was treated with tetraform. The usual spleen mixture followed by arsenic and iron, generally cacodylates and Fraisse's ferruginous ampoules, were given.

We got very good results from cacodylates especially. Aolan was given to stimulate the reticulo-endothelial system in some cases. The spleen decreased in size, and the condition of the blood and general condition of the patient improved. Medical treatment was then discontinued and only bitter tonics with strychnine and plenty of milk ordered. When the patient was considered ready, liberal doses of glucose were given for three or four days preceding the operation.

The operation

'The removal of the spleen may be an operation of the greatest simplicity or of almost insuperable difficulty. Everything depends on the presence or absence of adhesions which may bind the organ inseparably to the parts around' (Moynihan). In my cases general anæsthesia with chloroform only, *faute de mieux*, has always been used. The incision I make has always been the left paramedian, extending from the costal arch to half-way between the umbilicus and the symphysis pubis, but in case of very big enlargement of the organ to the latter bone. The rectus is pulled outwards and the abdomen opened in the line of the incision. Even in the case of the biggest spleen measuring, while fresh, 13 by 10½ inches I did not experience much difficulty, though I dare say a vertical paramedian extending at right angles or obliquely outwards might give better exposure. Even a -shaped incision may be

made, the vertical line being a paramedian or a median one. But I think a vertical incision gives a better view of the pedicle, where the most difficult and important steps of the operation lie. As soon as the peritoneum is opened, the liver and gall-bladder are rapidly examined, the amount of enlargement and the degree of cirrhosis, if any, noted. The pedicle is next examined and the nature of adhesions determined. The right hand is now passed on to the convex upper and outer surfaces of the organ to examine the density of the adhesions. The operator has now to make up his mind if he can safely remove the spleen; the attempt should be abandoned if he finds it impossible to sever the adhesions, or if laceration of the spleen in an attempt to do so seems unavoidable. If in doubt it would be better to give up the attempt.

Now the removal of the spleen may be accomplished by one of two methods:—(1) Separation of the adhesions on the upper and outer surfaces of the organ, its delivery outside the abdomen, and finally ligation of the pedicle; this is the method of choice.

(2) Ligation of the pedicle first, freeing all other adhesions, and delivering the organ when it is absolutely free; this method is to be preferred where the adhesions are dense and the

spleen friable. Uncontrollable hæmorrhage may occur if the splenic vessels are not ligatured first before the adhesions are freed, either from (a) the separated adhesions, or (b) tearing of the splenic tissue, or (c) from a torn vein of the pedicle where these enter the hilum. On the other hand access to the pedicle is more difficult and the tail of the pancreas is more likely to be injured or ligatured. The latter lies touching the spleen, or even adhering to it and to the pedicle, but under it, and can be better defined from behind. In my earlier cases I used only the latter method, but with more experience I use whichever method seems to be better suited to the case.

The following method will perhaps be found suitable for most cases. Define the pedicle first, separate all adhesions of the omentum to the spleen between series of ligatures. Big veins will often be found coursing through them, sometimes as big as one's finger. Adhesions may be light or dense, few or many. The gastro-splenic omentum which contains the vasa brevia vessels is defined if possible (it often merges into the other adhesions) and divided; the adhesions to the stomach are dealt with, taking care not to injure the organ. The left gastro-epiploic artery should be saved if possible, this really does not matter very much as the blood supply of the stomach is abundant, specially in most cases of enlarged spleen. According to Millar it may be an advantage to ligature this artery, as it might reduce hæmatemesis in cases of splenic anæmia. Now the pedicle comes into view clearly and the vessels can be ligated separately, this should be done between ligatures. It is better not to use any clamps in this area, as softened veins might be torn by the clamps. The splenic artery should be ligatured first, if possible, but I find that any attempt to do this leads to severe bleeding from torn veins. Similarly separating the pancreas also very often causes hæmorrhage. On one occasion I had to tie off the tail of the pancreas to save the patient's life from hæmorrhage, with no other apparent ill effect than a sharp rise of temperature and some pain lasting for four or five days. The veins in malarial enlargement are thin and may cut through when a ligature is applied. Nowadays I use no. 3a or no. 4 catgut for ligaturing the pedicle vessels. In one of my cases the main vein was cut through three times—at last I wrapped a piece of omentum round it and applied a double thick ligature, which luckily held. Sometimes the veins after ligaturing may look like Oxford sausages; my advice is to leave them alone and not to handle them.

If the pedicle lies very deep or cannot be conveniently dealt with for any other reason, I leave it alone and proceed with the separation of the other adhesions. This division of the pedicle may be a simple matter, but more

often it is a most difficult and painstaking bit of surgery. The whole right hand is now passed above the upper pole, gently separating the adhesions; by carefully working with the right hand and pulling away the organ with the left, bands may be made to form, which are clamped and divided. One such band is called the phrenico-splenic ligament; this often contains small vessels. Next the hand sweeps over the outer surface of the organ, separating adhesions, and, if bands form, these are clamped and divided. The spleen is now delivered and wet hot towels are packed into the empty space to check oozing which is considerable at first. This is very important. The pancreas is next defined and isolated. The vessels of the pedicle are picked up separately or at least in groups, ligatured and divided. Massive ligature of the whole pedicle should never be attempted—the results will most likely be disastrous. Some of the vessels will most likely either rupture or slip out of the pedicle. I often apply two separate ligatures on big vessels in case one cuts through or slips off. The spleen is now free and is removed. The pancreas is examined carefully to see if there is any bleeding. The hot packs are removed and the empty space is carefully examined for any bleeding points. The clamps, if not already removed, are taken away after ligaturing the bands previously referred to. A bleeding point on the under surface of the diaphragm can be secured with the help of a fine needle and catgut, using Lembert stitching. During all these manœuvres the utmost gentleness should be exercised.

Spleens removed by writer.

There should be no pulling or torsion of the pedicle and the spleen should be handled with the greatest care, to obviate tearing or rupturing of veins, or of the spleen itself. The abdominal wound is now closed in layers in the usual way, using Michel's clips for the skin, as time is saved thereby. No drainage is used. The appendix may be removed, if it is considered necessary and if it is not likely to prolong

the operation for more than three or four minutes. Although I always remove the appendix as a routine in all other laparotomies, I generally leave it alone in splenectomies.

For the after-treatment plenty of glucose-D is relied on.

Special dangers

The greatest danger of this operation is hæmorrhage, not so much from the greatly dilated vessels of the pedicle, but from accessory veins in the capsule of the spleen which form in the adhesions between the convex surface of the spleen, especially at its upper pole, and the diaphragm or the abdominal wall, and also from a torn or lacerated pancreas. Death from thrombosis of the portal vein is also said to occur. As the liver is also affected there is also danger of failure of the liver function after general anæsthesia. This may be avoided by giving gas and oxygen but, as nitrous oxide is not available in India, it is very difficult to obtain adequate supplies. The general health of the patient is as a rule poor and he is anæmic, so shock has to be combated. Slight laceration of the tail of the pancreas is sometimes unavoidable.

The one patient I lost died of hæmorrhage; during the operation there was smart oozing from the under surface of the diaphragm which stopped after pressure with a very hot towel. The oozing had commenced again and must have been considerable, from the findings during post-mortem examination. The adhesions in this case were very dense and I would have given up the attempt had I not already dealt with the pedicle.

Complications.—Two patients developed pneumonia, two hepatitis and two a relapse of malaria, but of these one patient had both pneumonia and hepatitis and another hepatitis and malaria, so that only four patients had complications. One died of hæmorrhage the day of the operation and five recovered without any trouble.

Ligature of the splenic artery only.—I have no experience of this. Many observers have suggested it but few have practised it. The only surgeon who definitely condemns it is Benhamou in his book *L'Exploration Fonctionnelle de la Rate*; he says necrosis is sure to follow. In my opinion it is too risky and, even if the patient recovers, collateral circulation will surely be established and the diseased spleen will be left to carry on its nefarious work.

After-treatment.—This is the same as in all laparotomies. Usually patients have not been given any special treatment to build up their blood, such as liver or liver extracts, meat juice, or even iron and arsenic after the operation, as we wanted to note the result of the splenectomy alone, these operations being in the nature of surgical research, but of course

there have been exceptions. We have never been disappointed so far in the results of the operation. Patients who do not develop complications steadily improve in health till they are discharged or want to go away for domestic reasons. The average stay in hospital after the operation has been 44 days and before operation about seven weeks. Five of the patients have been seen recently and were in excellent health.

CASE REPORTS

(i) *Malarial enlargement—intracapsular laceration.*—Dhobi S., male, aged 26 years, was admitted on the 28th October, 1932, for a huge cystic tumour filling the whole abdomen. The enlarged spleen could be felt along the left border of the cystic swelling. The abdomen was markedly protuberant specially above the navel. 'Ruptured spleen' was suggested but the diagnosis was not accepted.

Previous history.—The patient gave a history of repeated attacks of fever with rigors for the last five years. The spleen became very enlarged. Once it was massaged and after that it became tender and the whole abdomen swelled up. This happened a year previously and since then he had been laid up in bed. (This statement was accepted with reservations at the time.) He was very emaciated and jaundiced. He was treated with quinine, spleen mixture, iron and arsenic, etc.

The patient was operated upon on the 1st December, 1934. A left paramedian incision extending from the costal arch to a point two inches from the symphysis pubis was made. On opening the abdomen a large dark-blue cystic swelling was seen which burst as soon as I tried to manipulate it. The cyst was full of fluid and clotted blood. There was severe hæmorrhage, the cyst was plugged with towels and the pedicle was tied as quickly as possible. A big vein ruptured and had to be tied again.

The spleen without blood or clots weighed 5 pounds 12 ounces and measured 13 inches by 10½ inches by 8½ inches. The liver was enlarged two finger-breadths below the costal arch. Convalescence was uninterrupted except that he had a relapse of malaria and benign tertian parasites were found in his blood. He was treated with quinine and atabrin.

Blood counts:—

	7-11-32.	11-1-33.
	Per c.m.m.	Per c.m.m.
Red blood cells ..	3,200,000	4,100,000
White blood cells ..	4,375	11,000
	Per cent	Per cent
Polymorphonuclears	53	42
Lymphocytes ..	35	47
Hæmoglobin ..	60	75

The patient improved in health and strength and was discharged on 26th January, 1933. He is a coolie working in the bazaar and used to come regularly once every three months for examination. He was doing hard work and earning his livelihood two months after the operation. He is in perfect health now. He has had no relapse of malaria.

(ii) *Malarial spleen with complications.*—M. S., male, aged 22, resident of Balasore, admitted on the 1st February, 1933. Had enlarged spleen for the last eight years. Used to have fever with rigors but not lately. Spleen was hard, movable, extended 3 inches below the level of the umbilicus. Liver extended 3 finger-breadths below the costal arch. Slight jaundice. Operation on the 3rd March, 1933. The surface of the liver was reticulated. There was a small accessory spleen, the size of a golf ball, which was also removed. The spleen was fairly adherent, bled freely, bleeding was stopped with ligatures and hot packs.

The next day he had a sharp rise of temperature; benign tertian parasites were found. After a fortnight he got hepatitis and jaundice and was treated with emetine, etc. Later he got a pneumonic patch at the right base, and still later pleurisy; blood-stained fluid was aspirated. However, he recovered from all these and was doing well. On receiving a telegram from home he left on the 23rd April, 1933.

Blood counts:—

	24-2-33	23-4-33
	Per c.mm.	Per c.mm.
Red blood cells ..	3,700,000	4,200,000
White blood cells ..	3,000	7,200
	Per cent	
Polymorphonuclears	65	
Lymphocytes ..	30	
Hæmoglobin ..	65	

The spleen weighed 5 pounds 6 ounces and measured 12 inches by 10 inches. The spleen marked 'S' belonged at one time to this patient. He wrote some time afterwards, in reply to our letter, to say that he was in good health.

(iii) *Splenomegaly of doubtful origin*.—N. S., male, aged 15 years, resident of Puri, admitted on 14th September, 1933. Had a very large spleen for the last seven years. No definite history of rigors, only occasional attacks of fever. The spleen on admission nearly touched the symphysis pubis; one could hardly push a finger between the spleen and the bone. The patient was very anæmic. There was a heavy ankylostoma infestation. He was in the medical ward for three months and had many forms of treatment, viz, spleen mixture, Fraisse's ferruginous ampoules, cacodylate liver, raw meat juice, etc. The spleen was reduced in size by about two inches, the patient improved in general health, so operation was decided upon at the request of the boy's father, though he was still a grave surgical risk.

Operation on the 24th January, 1934. A left paramedian incision extending from the costal to the pubic arch was made. Liver was four fingers below arch, looked very congested. The omentum was adherent to the gall-bladder, though no calculus could be felt. There were far too many adhesions, the omentum was adherent to the spleen all over, the spleen was firmly adherent to the diaphragm and abdominal wall. A vein ruptured during manipulation and there was smart hæmorrhage. The spleen weighed 4 pounds 8 ounces, measured 10½ inches by 6 inches by 4 inches. Blood count on different dates was as follows:—

	31-9-33	4-1-34	19-2-34
	Per c.mm.	Per c.mm.	Per c.mm.
Red blood cells ..	3,200,000	4,200,000	4,300,000
White blood cells ..	8,400	5,625	11,250
	Per cent	Per cent	Per cent
Polymorphonuclears	47	56	62
Lymphocytes ..	17	25	24
Hæmoglobin ..	50	65	75

The liver was reduced and the patient made an uninterrupted recovery. The father of the patient took him away on 19th February, 1934, though I should have liked to have observed him for a little while longer. He was seen at Puri during the Ratha Jatra festival and appeared to be quite well.

(iv) *Splenomegaly—presumably splenic anæmia*.—G. P., male, aged 40 years, cultivator, admitted on 4th May, 1933. Had enlarged spleen for the last two years, but not much fever and no rigors. Slight jaundice. Liver tender, 7 finger-breadths below costal arch. Urine high coloured and scanty. Gave history of melæna and hæmatemesis.

Blood count:—Red blood cells 2,900,000, hæmoglobin 55 per cent, white blood cells 5,625, polymorphonuclears 58 per cent, lymphocytes 30 per cent.

Pre-operative treatment had no effect on the blood count. Operation on 27th June, 1933. The spleen felt to be firmly adherent to the under surface of the diaphragm; adhesions all round were numerous and dense. While examining a big vein it ruptured and the pedicle had to be tied first, so when I found the dense diaphragmatic adhesions I had no option but to proceed with the operation. There was much oozing from the diaphragm which partially yielded to pressure with very hot towels. Lambert stitches were tied, but could not have been very successful, as the patient bled to death during the night. At the post-mortem examination it was found that the whole of the denuded diaphragmatic area had bled profusely. The liver showed slight hobnailing, but the surface was markedly reticulated, there were hard white lines round the protruding hobnails. The stomach wall was thickened.

(v) *Splenomegaly—origin doubtful*.—G. S., male, aged 30, admitted on the 14th September, 1933. Occupation peasant farmer, but had been working as durwan in East Bengal for the last eight years. About five years previously he had been having fever, with or without rigors; had a lot of medicines and a few injections. Became very weak and emaciated and left Bengal. Since then he had been getting fever now and again; spleen kept on increasing in size and he had not been able to do any work. He had been a muscular man at one time. He might have been a case of kala-azar, but the aldehyde and urea-stibamine tests were negative. Quinine, iron, etc., did not have much effect, but a course of 12 cacodylate injections caused the size of the spleen to be reduced somewhat and brought about a marked change in his general condition. He was operated upon on 24th October, 1933. The adhesions were extensive but were easily dealt with; the spleen weighed 4 pounds 1 ounce measured 9 inches by 6 inches by 4 inches. Blood count at different times was as follows:—

	2-8-33	23-10-33	15-12-33
	Per c.mm.	Per c.mm.	Per c.mm.
Red blood cells ..	2,700,000	3,600,000	4,300,000
White blood cells ..	5,000	6,500	9,375
	Per cent	Per cent	Per cent
Polymorphonuclears	54	60	52
Lymphocytes ..	30	28	32
Hæmoglobin ..	50	65	80

The liver was two fingers below costal arch when admitted and at the time of operation it showed a distinctly reticulated surface. Soon after operation he developed hepatitis and the liver enlarged further to four finger-breadths below costal arch. The inflammation subsided with emetine, quinine, liver tonics, etc., but the enlargement remained.

Three months after operation the liver was still tender and was further enlarged to seven fingers below costal arch. Otherwise the patient was fairly healthy and had put on weight. He was discharged on 4th January, 1934, on account of misconduct.

Seven months after operation he came again to see me as I had promised him a wardship in the Jail if he got fit again. Liver was not tender but still three fingers below the costal arch though only at the gall-bladder area.

Ten months after operation the liver could only be felt just near the gall-bladder, about one finger-breadth enlargement below and about two fingers wide. Again he claimed the promised wardship. On being told that the liver must be perfectly healthy before he could be given a wardship, he requested that his liver should be removed as otherwise he is strong and healthy.

EPIDEMIC MEASLES IN ASSAM

By D. MANSON, M.B., Ch.B., F.R.E.S.

Chief Medical Officer, Jorehaut Tea Company, Limited
Cinnamara, Assam

Introductory.—During the spring of 1934, the province of Assam was visited by a severe epidemic of measles, mostly prevalent amongst the labour forces of tea gardens and the inhabitants of neighbouring *bastis*. The epidemic soon assumed pandemic proportions in Assam, continued throughout the remainder of the year and extended into 1935. At the time of writing, this pandemic is still active, although in many places it has tailed off, and, in some districts, has now completely ceased. The disease was prevalent in varying degrees of incidence and severity in both the Assam and the Surma Valleys.

It is difficult to find records of former epidemics, but Assam has not been visited by such a widespread wave of measles within the last 12 years.

Literature on measles in the tropics is scanty and the object of the present article is to record the present epidemic and its main features, for comparison with similar epidemics in colder climates. Particularly it is desired to point out the effects of different treatments both as regards prophylaxis and cure.

It is not proposed to include a survey of the whole epidemic but merely to confine observations to measles in the group of tea estates which are under the writer's personal medical control.

Segregation.—The difficulties which attend all attempts at complete segregation of measles cases and their contacts on tea gardens will be too well known amongst those who have had to deal with similar labour forces to need any emphasis. The average Assam coolie is ignorant of any laws regarding segregation and, however rigorous the steps taken to secure this may be, the end-results, in most cases, are disappointing.

When the number of cases on any garden is large, segregation becomes increasingly difficult and the necessity for leaving a sufficient labour force available to carry on the essential work of the garden becomes a real problem in economics. Most tea-garden managers adopt a definitely pessimistic attitude towards segregation *per se*, and, although this is not advocated from the correct medical point of view, some reasonable compromise is generally accepted as the final solution.

In the present epidemic, as far as my own group of gardens was concerned, segregation was carried out as rigorously as was humanly possible, although, in some instances, a widespread attack of measles in the lines rendered segregation difficult and abortive.

Thirteen gardens under my medical care were affected.

Epidemiology

Date of origin.—The first appearance of the present epidemic of measles in the province was registered on 2nd February, 1934, in the Surma Valley and on 7th March, 1934, in the upper or Assam Valley. The first case of measles reported in this district was on 29th May, 1934, and, for some time, measles was confined to this garden, but was prevalent on neighbouring gardens not under my supervision; this case was a coolie who had returned from a visit to friends on a measles-infected garden in another part of Assam.

This seemed to present an opportunity where rigid segregation could be attempted with a reasonable expectation of success, and accordingly all the usual steps were taken without delay. Success seemed probable, but as almost certainly other cases had already had contact with measles from outside sources, partial success only was attained.

Neighbouring gardens of the company were not affected until a much later date, and thus, up to a point, a modicum of success must be attributed to the prophylactic measures taken. Later, the epidemic was continued by the spread of measles from surrounding areas, and finally every garden in the group paid tribute to the scourge.

Incidence of measles.—Table I shows the incidence of measles on each garden and the percentage of the total population affected. The gardens are numbered in the sequence in which the disease manifested itself. The dates of previous epidemics are also recorded in the last column.

From the table it will be seen that the first appearance of measles was on a garden which had been visited with a severe epidemic of measles in September 1930. This accounts for the small number of cases on the garden, as the immunity conferred by the previous severe epidemic limited the occurrence of a further outbreak. Garden 2 which had no such immunity was the focus of a severe epidemic which affected 12.7 per cent of the total population. The measures taken on this garden to isolate it from its neighbours were evidently fairly successful as no further outbreak of measles occurred until garden 3 was infected on 15th August, 1934. This infection was brought from an outside source and in no way induced by the epidemic on garden 2. This is borne out by the fact that the three gardens which adjoin no. 2 estate were not infected until 1st October, when garden 2 had been clear of measles for four weeks. Garden 3 was remote from no. 2 and adjacent to an infected garden outside my jurisdiction.

Measles continued until all gardens were affected and it is still present on two gardens in the group.

TABLE I

Number of gardens	Date of commencement	Total population	TOTAL CASES OF MEASLES		Percentage of population affected	Number of deaths	Percentage mortality	Date of last epidemic of measles
			Children under 12 years	Adults				
1	28-4-34	1,093	5	..	0.46	nil	..	June 1930.

11	12-12-31	674	19	2	3.12	1914.
12	1-1-35	1,706	7	..	0.41	June 1928.
13	29-2-35	1,017	25	2	2.05	3	11.11	1929.*
GRAND TOTAL	..	18,408	789	64	4.63	19	2.23	*Few cases only.

Complications

The incidence of complications varied from garden to garden; in garden 10 it was as high as 38.54 per cent and in garden 2 it was only 8.00 per cent. In the whole group, 150, or 17.58 per cent, had complications.

Table II shows the type of complication present and the relative percentages in which they occurred.

TABLE II

	COMPLICATIONS		DEATHS	
	Number of cases	Percentage of total	Number	Percentage of total mortality
Broncho-pneumonia ..	46	30.66	9	47.38
Colitis and diarrhoea ..	46	30.66	4	21.06
Bronchitis ..	19	12.67	1	5.26
Ophthalmia ..	12	8.00
Otitis media ..	6	4.00
Laryngitis ..	5	3.33	1	5.26
Œdema of glottis ..	1	0.67	1	5.26
Otorrhoea ..	5	3.33
Panophthalmitis ..	3	2.00
Furunculosis ..	2	1.33
Whooping cough ..	1	0.67
Abortion ..	1	0.67
Heart failure ..	1	0.67	1	5.26
Dysentery ..	1	0.67	1	5.26
Cancrum oris ..	1	0.67	1	5.26
TOTAL ..	150	100.00	19	100.00

Mortality

Table II shows the percentages of mortality arranged according to the cause.

The pulmonary group thus accounted for 52.64 per cent of the mortality. One patient died of œdema of the glottis of very sudden

onset. This is a rare complication and usually occurs in the prodromal stage. Two cases were recently reported by Oliver and Turner (1933). Cancrum oris occurred in one case and is almost a hopeless proposition as far as treatment is concerned.

The percentage mortality on each garden is shown in table I.

It is evident from this table that there was no lessening in mortality late in the epidemic as garden 13, the last in which measles occurred, shows a heavy mortality from broncho-pneumonia. The total mortality from the epidemic was 2.23 per cent. Osler states that the usual mortality is from 2 to 3 per cent in private practice and from 6 to 10 per cent in hospitals. The low mortality is in striking contrast to the terribly fatal epidemic of measles in the Fiji Islands in 1875 when 40,000 deaths occurred in 150,000 cases within four months. From investigations in London, Stocks (1933) adduces evidence that epidemics are terminated by the development of temporary latent immunity in children.

Age incidence of deaths.—Table III shows age incidence of deaths and percentages at each age.

TABLE III

Age at death	Number of deaths	Percentage
Under 6 months
6-9 months ..	2	10.53
1-2 years ..	8	42.10
2-3 " ..	4	21.05
3-4 " ..	3	19.79
4-5 "
5-6 " ..	2	10.53
Above 7 "
TOTAL ..	19	100

The highest mortality occurred in the period from 1 year to 4 years and there were no deaths in children over 7 years or in the adults attacked. Severity of symptoms in adults was not noteworthy although this is a common superstition amongst Europeans.

Age incidence of measles.—The age incidence is given in detail in table IV. From this it will be evident that there is a relative immunity in young children up to six months old and even up to 1 year and that the heaviest incidence occurred in the age period between 1 year and 8 years.

This corresponds closely with epidemic figures in temperate climates. The small proportion of adult cases is striking in comparison with the severe epidemics in the Faroe and Fiji islands where unprotected adults of all ages were attacked. Relapses were not recorded during the epidemic.

Caste incidence

There was no evidence of caste immunity; all were equally affected.

Seasonal prevalence of measles in the East

Leonard Rogers gives the following distribution of measles in the European Hospital, Calcutta, during the three years 1904 to 1906.

January ..	25	July ..	2
February ..	24	August ..	7
March ..	49	September ..	4
April ..	31	October ..	4
May ..	12	November ..	13
June ..	5	December ..	19

TOTAL .. 195

Five-sixths of his cases occurred in the six cold weather months from November to April.

In the present epidemic, the seasonal prevalence is shown in table V.

TABLE IV

* This column has been added since the paper was written.

In the present series 552 cases out of 853 occurred between November and April, a percentage of nearly 65.

It will be seen that the heaviest incidence occurred from September to March and that many cases occurred in the relatively hot months of September and October. Judging from the present figures, and from those of two smaller epidemics in 1928 and 1930, the lowest incidence of measles in Assam occurs in the spring quarter, April to June. Most epidemics seem to commence late in May or early in June, and the appearance of definitely cold weather does not limit the prevalence of the disease.

Clinical observations

Average duration of rash.—This was 3 to 8 days throughout the whole series.

Koplik's spots.—These were found in 67.4 per cent of all cases.

Type of desquamation.—This was the usual fine, branny type, except in 8 cases which showed large flaky desquamation.

Presence of rash.—Rash was present in all cases excepting 7 in which the general symptoms were very severe and in all of which diarrhoea was very troublesome.

Blood picture.—Leucopenia was present in all cases examined and in 100 cases examined by the Tallqvist method there was a development of progressive anaemia, which rapidly disappeared on convalescence.

Stancanelli (1934) found a diminution of haemoglobin and red blood cells in the prodromal stage with an increase in leucocytes in the eruptive stage. He found a shift of the Arneth scheme to the left in the eruptive stage and during complications.

In the present series, the following Arneth count was made in four cases:—

ARNETH COUNT OF MEASLES CASES AT CINNAMARA. 1-2-35

Case number	1	2	3	4	5 lobes	Index
1	70	28	2	0	0	99
2	82	16	2	0	0	99
3	78	20	2	0	0	99
4	89	9	2	0	0	99

Treatment

Treatment was carried out on general lines as regards routine treatment, but an attempt was made to test the efficacy of (a) amidopyrin, (b) intensive vitamin-A administration, and (c) the effect of prophylactic convalescent serum, in limiting the spread of the epidemic.

Amidopyrin.—Collier (1930) recommended the use of this drug, which had been previously tried by Loewenthal (1924) in measles. He used pyramidon in powder given at four-hourly intervals during the day and night. The dosage recommended was 15 grains per adult with the usual formula dosage for children according to

age; the doses given were 2 to 5 grains. He claimed a specific action for this drug and an absence of complications with this treatment has been reported by further observers. Other clinicians advocated a smaller dose of 1 grain per year of age with a maximum of 4½ grains, given four-hourly.

In the present epidemic, and in a former epidemic on garden 1 in 1930, amidopyrin was used in the doses recommended by the above observer, but they were found to be far too large for safety in coolie children. The effects were generally beneficial, but cases of collapse occurred with the larger doses and the treatment was modified to a dosage of gr. i thrice daily for children up to 6 months and grs. ii for children from 2 to 5 years, with proportionate doses for older children.

Reports of my assistants on the efficacy of the drug varied. In some cases the results seemed favourable and the duration of the febrile period was shortened. In others there was no diminution in the average febrile period. In no case was the incidence of complications affected by the dosages used. In some cases, the temperature fell more rapidly than usual but there was a greater tendency to the development of diarrhoea in such cases. It may possibly be that the dosage used was too small, but an increase seemed to be contraindicated in view of the collapse symptoms which followed the larger doses.

Recently, a further disadvantage of this drug has been disclosed by the publication of cases treated with amidopyrin which have developed agranulocytosis. On the other hand, the compound powder, acetyl-salicylic acid—5 grains, compound powder of ipecacuanha—2½ grains, and phenacetin—2½ grains, was more efficacious, it lessened the urgency of symptoms and also complications in a series of cases in which it was tried. These amounts were used for adults and proportionate doses for young children thrice daily.

Atebrin.—This was given in one case which showed malarial infection and a considerable amelioration of the general symptoms was observed. Subsequently atebrin was tried in a further series of 8 cases without malaria, and again there was a definite improvement in the symptoms with decrease in temperature. None of these cases developed complications. This series is too small to be conclusive, but this drug certainly merits a further trial; the results were distinctly encouraging.

Omnadin.—Five cases were treated with omnadin 1 c.c.m. by injection daily for 3 days, and showed a reduction in temperature with no complications ensuing. The series is again too small for conclusive results but the improvement in symptoms warrants a more extensive trial of this compound.

Vitamin A.—On garden 2, cod-liver oil in emulsion was given to all cases, and, in addition, as a prophylactic to all children in the

lines. The dose used was equivalent to 5i to 5vi of cod-liver oil daily for children from 1 year to 12 years according to age. The percentage of infection in this garden to total population was 18 and the percentage of complications, which were very slight, was 18.75. The results were distinctly beneficial. Diarrhoea and colitis were not affected unfavourably by this mode of treatment. The number of cases treated was 112 and the number of line children was 200. There was only one death, the death rate being only 0.89 per cent. Vitamin-A treatment did not limit the spread of the disease, but it appeared to reduce the severity of complications and consequently the death rate.

Prophylactic serum.—On garden 2, which was visited early in the epidemic, there were 125 cases of measles out of a total population of 984 which included 365 children under 12 years of age. As this garden had no history of epidemic measles within 14 years, the presumption was that the disease was likely to run completely through the lines. It was therefore decided to try the use of prophylactic convalescent serum. Osler and McCrae recommend serum from cases which have had a normal temperature for 5 to 10 days in doses of 2.5 c.cm. for 4 days and 4 c.cm. on the 5th and 6th days.

Orvosi more recently recommends 3 to 10 c.cm. of serum collected 6 to 8 days after defervescence. Recently, 2 to 3 c.cm. on 3 consecutive days has been advocated. The larger doses seem contraindicated and the smaller seemed to act well. There were no adverse symptoms following injection and no complaints of pain or subsequent fever. Serum was obtained from measles cases which had been convalescent for 7 or 8 days. The dosage used was 3 to 5 c.cm. by intramuscular injection according to age. Each batch of serum was collected, tested for sterility and, in every batch, a preliminary Kahn test was made to prevent the possibility of the transmission of syphilis. The results were distinctly good. Out of 185 cases inoculated, only 5 developed measles, two of these within 2 days of inoculation.

It is almost a certainty that, had this prophylactic serum not been used, the number of cases would have been much larger. This is borne out on considering the results in garden 3, which followed with a record of 251 cases of measles amongst a population of 350 children. This garden population was not protected by prophylactic convalescent serum. Here the percentage of measles cases to total child population was 70 per cent, as against 33 per cent on the garden where convalescent serum was exhibited. The initial immunity in each garden was presumably the same and segregation was carried out on closely similar lines in both instances.

A NOTE ON AN EPIDEMIC OF CEREBROSPINAL FEVER IN A CLOSED COMMUNITY

By R. B. LAL, M.B., B.S., D.P.H., D.T.M. & H., D.B.
and

M. YACOB, M.B., B.S., D.P.H., D.B., D.P.H., D.T.M. & H.
(From the Punjab Epidemiological Bureau, Lahore)

Historical.—It is over half a century ago that Vandyke Carter, while engaged in his studies on relapsing fever in Bombay, described four cases of cerebrospinal fever in this country. Dimmock recognized the disease in epidemic form amongst the convicts of Shikarpur gaol during the winter of 1883-84. It is, however, surprising that since that time very little literature has appeared on the subject in India. In fact, it seems that this disease has somehow failed to engage the serious attention of the profession. Practically all the recorded outbreaks of cerebrospinal fever are in gaols

(Continued from previous column)

Summary

An account is given of a measles epidemic in Assam with tables of incidence, mortality, and seasonal incidence.

The effects of amidopyrin, vitamin A, atebirin and omnadin in treatment are discussed.

A note is given on the efficacy of convalescent serum as a prophylactic measure.

Conclusion

Measles in the tropics follows closely the type of the disease in temperate climates with a greater seasonal distribution in the hot weather months.

The use of cod-liver oil in treatment and of convalescent serum in prophylaxis is strongly advised.

Acknowledgments

I have to thank Dr. C. R. Das Gupta, of the Calcutta School of Tropical Medicine, for carrying out the Arneeth counts, and to Dr. L. R. Dey, Cinnamara Central Laboratory, for his help in preparing the statistics.

and army barracks, where, on account of the comparatively closed nature of the community, high case mortality and dramatically sudden fatality, even a few cases of meningitis attract the immediate attention of the authorities. Moreover, the greater facilities for diagnosis available for these institutions soon reveal the true nature of the disease. On the other hand, factors, such as its irregular distribution both in space and time, and lack of laboratory facilities or neglect on the part of medical practitioners to use laboratory methods for diagnosis, would seem to suggest that the paucity of records of cases of cerebrospinal fever may not necessarily indicate that the disease is limited to institutions and that the civil population is to be regarded as free from the disease.

In our own province previous to 1920 no records of the occurrence of cerebrospinal fever are available. In that year, however, thirteen cases were admitted into the Mayo Hospital, Lahore. All of them were Kashmiri Moham-medans who had come from Jammu State. During the decade, 1921 to 1931, a few sporadic cases of cerebrospinal fever were occasionally reported from Ambala Brigade area, Rawalpindi, Lahore and Multan cantonments, but no outbreak of any importance occurred during that period.

The present outbreak.—In March 1932, however, an epidemic of cerebrospinal fever occurred in the Borstal Institution at Lahore. During the course of this epidemic which covered a period of about two years small outbreaks with intervening quiescent periods continued to occur. The first two cases were reported on the 12th of March 1932. Altogether 27 cases and 11 deaths were reported up to 15th November, 1933. The distribution of cases by months is shown in table I.

The distribution of cases is also shown in the sketch map of the institution.

It will be seen that the largest number of cases was reported from the kitchen and circle I, i.e., 6 and 5 respectively, out of a total of 27 cases. It will further be noticed on reference to table V that the carrier rate was also subsequently found to be the highest in these two localities, i.e., 52.63 per cent in circle I, and 20.00 per cent in the kitchen.

The Borstal Institution is a provincial gaol, primarily meant for adolescent and juvenile offenders below 25 years of age. Accommodation is provided for 1,705 prisoners, 350 of whom are lodged in barracks and the rest are individually locked up in cells. High walls divide the residential portion of the gaol area into a number of enclosures known as circles. In each circle there are a number of two-storied buildings, each floor of which consists of a double row of cells set side to side and back to back. The individual cell which provides accommodation for a single prisoner is a room 15 by 8 feet, with an iron grating door $7\frac{1}{2}$ by $2\frac{1}{2}$ feet, and a ventilator $2\frac{1}{2}$ by $2\frac{1}{2}$ feet. The prisoners are locked in at sunset and are let out at sunrise into the big compound of the circle, where common latrine accommodation is provided. The inmates of the cells in each circle have thus an opportunity of mixing together for about half an hour in the morning and half an

hour in the evening, when they are collected together before being locked up for the night. Most of the prisoners have to spend about eight hours in the factories, all located in one big

compound. The sheds in which the prisoners work are all well ventilated and well lighted and on an average sixty square feet of space is provided for each person, though in practice they usually crowd up together for work. Besides the hours of work, the prisoners also closely associate with each other at the school and in the play ground. Some of the inmates

are put on special duties, e.g., cooks in the kitchens, attendants in the hospital, storekeepers in stores. They take their residence in the barracks situated near their place of work. A certain percentage of the men are on outdoor duty in the garden or on watch at night.

The gaol population at the time of the outbreak was 1,721, but during the preceding four months it had ranged between 1,800 and 2,489, that is to say the institution was overcrowded.

About the middle of November 1931, as a result of the Ahrar movement, large numbers of prisoners were received into the institution from various camp gaols in Jammu and Kashmir State. Some of these prisoners mentioned the occurrence of a somewhat similar illness in the Kashmir gaols.

Small as the number of cases appears, the persistence of the disease seriously dislocated the work of the institution, and, in order to avert the danger of a serious epidemic and to arrest its progress, help and advice of the public health authorities was sought by the gaol department. The preventive measures adopted to suppress the outbreak have already been dealt with in another communication by Chopra and Chadha (1933).

It is proposed to discuss here the bacteriological and epidemiological investigation carried out in connection with these measures.

The detection of carriers.—For the rapid detection of likely carriers, smears from the nasopharynx of 1,268 inmates were examined microscopically in March 1932, and about 20 per cent showed organisms morphologically indistinguishable from the meningococcus. The heaviest infection rate—65.6 per cent—was found in the kitchen. Towards the end of November a cultural examination was started. Nasopharyngeal swabs of 277 contacts were examined. As a result of this procedure 12 carriers were detected and isolated. In view, however, of the general epidemiological behaviour of the disease and the experience gained during the past year it was apprehended that the carriers of the meningococcus might not be confined to the 277 contacts already examined, but might be distributed throughout the population of the institution. Thus, there was a potential danger of an epidemic flaring up owing to a disturbance of the equilibrium of herd immunity, if a large number of admissions of non-immunes were made into a population containing many carriers, and the new-comers were allowed to mix with the existing gaol population. It was, therefore, decided that repeated swab examination of all the inmates of the institution, 835 in number, should be made by cultural methods. For this purpose, the gaol population was divided into groups according to their association at work and examination of one group was completed before proceeding with the other groups.

It was also planned that fresh admissions, which were to be made in batches of fifty,

should not be allowed until all the inmates had been examined and carriers isolated. Each fresh batch was to be quarantined for a fortnight and examined for carriers before admission into the general population of the gaol. Thus the number of prisoners examined up to 15th November, 1933, was 2,222 of whom 1,387 were fresh admissions.

Laboratory procedure.—*Neisseria meningitidis* is admittedly one of the most difficult organisms to deal with. The isolation of this organism specially when one is suddenly called upon to examine a large number of persons with as little delay as possible demands considerable forethought in devising a simple and efficient laboratory procedure and in organizing the work. As a similar situation may possibly arise elsewhere, we propose to describe the laboratory procedure adopted by us in some detail.

The workers were divided into four groups, each group having its own limited responsibilities and sphere of activity.

GROUP I.—MEDIA SECTION

Media used.—The medium found most satisfactory during the course of this investigation was blood agar prepared from sheep's blood. The blood used was etherized thrice on three successive days and was added to melted agar at 50°C. in a proportion of 5 per cent.

Dorset's egg medium was used for a short period for sub-culturing isolated strains of meningococci and keeping them in stock. We have not, however, found it in any way superior to the other media used. Growth on this medium was often meagre and did not last long.

Serum sugars.—During the early stages of the investigation liquid sugars were used. Subsequently, their use was given up in favour of a solid medium, consisting of serum agar containing 1 per cent of the carbohydrate. The latter gave more clear-cut and consistent results. Another great advantage was the ease with which contamination could be detected. It also appeared that the organisms of the genus *Neisseria* had a longer lease of life on solid sugars. Subcultures from liquid sugars were rarely successful after the fourth day, whereas in the majority of cases they were successful in the case of solid sugars up to the seventh day. It seems that autolysis occurs easily in liquid media.

GROUP II.—COLLECTION OF MATERIAL

A batch of fifty inmates was examined at a time. Three throat swabs of each prisoner were taken on consecutive days. West's swabs were employed for touching the nasopharynx, so as to avoid the injurious effect of the saliva on the growth of the organisms. Blood agar plates which had previously been warmed were lightly touched with the swab in one corner and the inoculum was spread on the rest of the surface by means of a platinum loop. The inoculated plates were immediately returned to a portable incubator and brought to the laboratory. Altogether 8,765 swabs were examined.

GROUP III.—PLATE EXAMINATION

Twenty-four hours' incubation was generally enough to enable us to recognize the colonies of *N. meningitidis* which appeared as circular, blueish-grey, translucent, convex, typically lenticular colonies, about 0.5 to 1 mm. in diameter, with an entire edge. They had a butyrous consistency and were easily emulsifiable. After confirmation by microscopic examination the colonies were picked up and direct inoculation on

blood agar slopes was made. After 24 hours' incubation the growth was tested for purity and if found satisfactory was submitted to further tests.

GROUP IV.—CULTURAL EXAMINATION

Solid serum sugar slopes of glucose, maltose and sucrose agar and a blood agar slope were inoculated to test the biochemical and cultural properties.

BIOCHEMICAL REACTIONS

The sugars were incubated at 37°C. for about 6 days. Fermentation generally appeared in 24 to 96 hours, rarely longer. For purposes of confirmation sugar tests often had to be repeated. It was observed that, in practically all cases, the meningococci soon dissociated on sugar media into two types of colonies, viz,

- A small dew-drop-like discrete translucent colony with an entire edge. The organisms usually gave an indeterminate reaction with a Gram stain.
- A colony, which after 24 hours tended to increase in size, developed a yellowish tinge and became somewhat opaque. Organisms from this type of colony gave a more definite Gram-negative reaction.

GROWTH ON BLOOD AGAR AT ROOM TEMPERATURE AND GROWTH ON NUTRIENT AGAR

On agar slopes or blood agar kept at room temperature there was no growth or sometimes perhaps a slight film or a few nodules at the point of heavy inoculation.

Of 975 strains of Gram-negative cocci examined 160 gave typical cultural and fermentation reactions, i.e., acidity in glucose and maltose, no change in sucrose.

SEROLOGICAL TESTS

Agglutination tests were carried out with all the emulsifiable strains of Gram-negative cocci irrespective of their sugar reactions. Polyvalent therapeutic serum obtained from Burroughs Wellcome and Company was employed in dilutions of 1/50, 1/100, 1/200, and 1/50 normal horse serum and normal saline were used as controls.

Auto-agglutination was observed to be a very marked feature of the *Neisseria* group as a whole. One hundred and twenty-eight strains, in which sugar reactions were negative for meningococcus, showed well marked agglutination in all tubes including the horse serum control and in some cases the saline control as well. Twelve strains with sugar reactions of the meningococcus also reacted in a similar manner. The results of the agglutination reactions of 149 strains regarded as meningococci on the basis of biochemical and other tests are shown in table IV. Of these strains 40.3 per cent proved to be agglutinable with the polyvalent anti-meningococcal serum while 59.7 per cent were inagglutinable.

TABLE IV

Agglutination reactions of organisms with positive sugar reactions

Total examined	AGGLUTINATION			
	Positive			Negative
149	1/50	1/100	1/200	89
	5	32	23	
	60			
	40.3 per cent			59.7 per cent

CARRIER RATE

(a) *The original gaol population.*—One hundred and three persons out of 835 were declared carriers, giving a carrier rate of 12.33 per cent. The carrier rate according to residence and occupations is given in tables V and VI.

(b) *Fresh admissions.*—By 12th May, the examination of the original gaol population having been completed and carriers isolated, fresh admissions of prisoners in batches of fifty per week were started. These were kept in quarantine for a fortnight. Their nasopharyngeal swabs were examined thrice for the presence of the meningococcus, and those found free were admitted into the institution and accommodated in circle IV. Any carriers detected were isolated along with the other carriers in the institution in one section, where work was provided for them and they were not allowed to mix with the population declared free from infection. One thousand three hundred and eighty-seven prisoners were admitted into the institution and examined up to 15th November, 1933; of these 9 were found to be carrying the

TABLE V

Miscellaneous	245	0	0.00
TOTAL ..	835	103	12.33

meningococcus and were declared as carriers, giving a carrier rate of 0.65 per cent.

Each carrier was examined weekly and was not declared free until six successive swabs were negative when he was permitted to mix with the free population.

Discussion.—It will be seen that the carrier rate amongst the original gaol population was 12.33 per cent, whereas amongst the fresh admissions it was only 0.65 per cent. It may be pointed out here that the fresh admissions consisted entirely of freshly-convicted persons and may, therefore, be regarded to a certain extent, as a sample of the civil population. Thus the carrier rate in the original population of the institution was about 19 times that of the fresh admissions.

A reference to table V shows that the carrier rate was highest in circle I and the kitchen, being 52.63 and 20.00 per cent, respectively. As regards the distribution of the carrier rate according to occupations the worst offenders would seem to be the tailors, dyers and sweepers, with carrier rates of 73.08 per cent, 60.0 per cent and 50.0 per cent respectively. No significance can, however, be attached to the high figures obtained in the case of dyers and sweepers, since the numbers actually examined are insignificant, being 5 and 4 respectively. Next in order are the carpenters and cooks with moderately high carrier rates, 25.2 and 20 per cent respectively. This is in accordance with expectations, since it will be observed on reference to tables II and III that the largest number of cases $5 + 6 = 11$ out of a total of 27 were also returned from these two groups. The high carrier rate amongst tailors, carpenters and cooks may to some extent be explained by the more intimate contact and conditions of overcrowding obtainable in the case of these groups, as compared with the other groups.

Summary

1. An outbreak of cerebrospinal fever occurred in the Borstal Institution, Lahore, during the years 1932 and 1933, resulting in 27 cases and 11 deaths. The infection was probably introduced by carriers amongst Ahrar prisoners transferred to the Borstal Institution from Kashmir and Jammu State gaols.

2. The largest number of cases, 6 and 5, occurred amongst the cooks and carpenters in the kitchen and circle I.

3. The bacteriological technique adopted during the course of the investigation is given. A solid serum sugar medium was found to be superior to a liquid medium for fermentation reactions. Eight thousand seven hundred and sixty-five nasopharyngeal swabs were examined by cultural methods for the detection of the meningococcus.

4. Of the original gaol population consisting of 835 inmates 103 were found to be carriers, giving a carrier rate of 12.33 per cent.

CLINICAL OBSERVATIONS ON CEREBRO-SPINAL MENINGITIS IN INDORE

By J. R. J. TYRRELL, C.I.E., M.B.

LIEUTENANT-COLONEL, I.M.S.

Inspector-General of Hospitals, Holkar State
and

HARI SHANKAR KAPUR, L.M.F.

In charge, Infectious Diseases Hospital, Indore

DURING the first half of 1934, cerebrospinal meningitis was reported in epidemic form from several parts of India, Indore being one of them.

Forty cases of cerebrospinal meningitis were admitted to the Infectious Diseases Hospital, Indore, Holkar State, between March and June.

The following note is based on the observations made during the epidemic.

Epidemiology

Age.—The majority were between the ages of 15 and 30. Except for two cases of about 50 years of age, no case above 50 years of age was admitted. Only two children, aged about 5 years, were admitted.

Season.—The epidemic was at its highest during the months of April and May; it then subsided. [It has only since reappeared in November and sporadic cases are still occurring.]

Sex.—There were thirty-two males and eight females.

Environment and spread of the disease

The first case was imported from Ahmedabad. Before admission to the hospital, he was

(Continued from previous page)

5. Of 1,387 fresh admissions consisting of newly-convicted persons 9 were found to be carriers, giving a carrier rate of 0.65 per cent.

6. Carrier rate was found to be the highest in circle I and the kitchen, amongst the tailors, carpenters and cooks, the latter two groups also showing the incidence of the largest number of cases.

Acknowledgments

Our thanks are due to Khan Bahadur Dr. K. A. Rahman, O.B.E., Director of Public Health, Punjab, for kindly placing at our disposal the records in his office dealing with cerebrospinal fever in the Punjab. We are also greatly indebted to Drs. D. R. Mehta, M. A. Pirzada, Abdul Haq, T. S. Gill and Ghulam Rasool for assistance during the course of this investigation.

REFERENCE

Chopra, P. D., and Chadha, M. S. (1933). An Account of the Epidemic of Cerebrospinal Fever in the Borstal Institution, *Indian Med. Gaz.*, Vol. LXVIII, p. 265.

kept at his house in Indore City for two days. The subsequent two or three cases came from the same or surrounding localities. None of the members of the families of the patients got the infection, except in one instance, when two cases occurred in the same family. The cases came from different localities of the city and were not confined to any single locality, nor community, but were mostly from amongst the poorer classes. Of the 40 cases, 4 were school boys, 3 cinema visitors and 3 mill-hands.

Schools, mills and places of entertainment were not closed.

Prophylaxis

None of the relatives attending on the patients got the infection. As a matter of routine, all of them were made to gargle twice a day with potassium permanganate solution. None of the hospital staff got the infection nor to the best of our knowledge did we act as carriers. Though we had no time for gargling as a rule, we invariably used the mouth-mask, when attending on these cases.

Symptomatology

To start with, the patients got catarrhal throat affections and in some cases they first got influenza-like symptoms and then the meningitic symptoms supervened. The commonest symptoms observed were fever, vomiting, continuous in the initial stage, severe headache, delirium, passing into coma and rigidity of neck.

Fever of an irregular type, sometimes touching the normal and then rising again to 102°F. or 104°F. Some of the patients died with hyperpyrexia.

Symptoms of intracranial tension:—Vomiting, mostly continuous in the initial stage, severe headache, delirium and coma.

Rigidity of neck:—The muscles of the back of the neck became stiff. The patient could not bend the head forwards nor could he move the head from side to side. As the disease progressed, the retraction of the neck became marked. The dorsal and lumbar muscles were in almost all cases similarly affected. In the worst of the cases, the back was arched with the concavity backwards and the legs were kept flexed. Pains frequently extended down to the muscles of the lower extremity.

Kernig's sign was usually present.

Hyperæsthesia, especially along the spine, and severe pain in the back were present in most of the cases.

Rash:—Purpuric spots were observed in a few cases.

Pulse:—The pulse frequency was not always proportionate to the degree of fever.

Inflammation of joints appeared, generally after a couple of days, in a few cases and then subsided without suppuration.

Cranial nerve implications were observed in a few cases such as pain in the ear, tinnitus and defective hearing, dilatation of the pupils and dimness of vision.

Herpes labialis was seen in a few cases.

Wasting:—In chronic cases there was marked wasting.

Cerebrospinal fluid:—On lumbar puncture, the cerebrospinal fluid was found to be turbid and in the worst cases it was purulent. It came out under pressure, its quantity generally reaching 30 to 40 c.cm. or even more and it contained meningococci.

The cases that recovered are not suffering from any permanent disability. Amongst the unfavourable signs are the occurrence of hyperpyrexia, irregular breathing and unduly prolonged period of illness.

Treatment

1. *Lumbar puncture*.—Lumbar puncture alone was found to be of value, as it helped in the draining of toxins and meningococci. For the first two or three days, it was done twice a day and then once a day, till the cerebrospinal fluid was clear and stopped coming out under pressure. In severe cases, where the cerebrospinal fluid was very thick, the cavity was gently washed with sterile normal saline solution.

2. *Serum*.—Polyvalent anti-meningococcal serum was given intrathecally in doses of 20 c.cm. or more, according to the severity of the case and the age of the patient. The serum was introduced into the spinal canal very slowly and on the slightest sign of shock the injection was stopped at once and the shock was treated with injections of adrenalin chloride solution. The amount of serum given was always less than the cerebrospinal fluid drawn, by about 5 to 10 c.cm. for fear of increasing the intracranial tension. If the cerebrospinal fluid withdrawn was not sufficient to permit the full dose of the serum being given intrathecally, the serum was given partly intrathecally and partly intravenously to make up the full dose. The foot of the bed was raised to allow the serum to run to the brain. The serum injection was repeated every day till the symptoms subsided, the cerebrospinal fluid was clear and the meningococci had disappeared therefrom. To lessen the risk of relapse, which occurred in a few cases, one or two additional doses of the serum were given after the meningococci had disappeared from the cerebrospinal fluid. The earlier the serum is given, the better are the results obtained. We mostly used serum from the Bengal Immunity and Bengal Chemical and Pharmaceutical Works.

3. *Soamin injections*.—Intramuscular injections of soamin solution in 1 grain doses were given on alternate days during the acute stage, guarding against gastric irritation and dimness

(Continued at foot of next column)

NEPHROSIS: ITS NATURE AND INCIDENCE IN INDIANS

By S. P. GUPTA, M.D.

Pathology Department, King George's Medical College Lucknow

NEPHROSES in general include all forms of degenerative types of Bright's disease. Nephroses are classified as follows:—

1. Primary or chronic or lipoid nephrosis.
2. Secondary nephroses.
- (a) Larval nephroses occurring in fever, early diabetes, anæmia and Graves' disease.

(Continued from previous column)

of vision. It is doubtful if this did any good.

4. *Sedatives*.—To induce sleep and give relief from severe headache and pain, potassium bromide gr. xx and chloral hydrate gr. x were given with very satisfactory results, the potassium bromide being repeated, if necessary.

5. *Nutrition*.—Plenty of nourishment by mouth, such as milk, fruit juice, eggs and glucose water, were given at frequent intervals.

6. *Urotropine*.—Urotropine, given by mouth as well as by intravenous injections, has been found of little value.

Mortality.—Of the 40 cases treated at the hospital, 10 died, the mortality rate thus being 25 per cent.

Conclusions

For some years past, a few cases of this disease have been detected each year in Indore City.

During the period under review, there was undoubtedly an epidemic, but it is equally certain that some of the cases would have gone undetected or been diagnosed as something else, if it had not been for the special precautions taken owing to the prevalence of the disease at Ahmedabad and elsewhere.

Our experience here shows the disease is not contagious and that there is no proof of the theory of dissemination by carriers. The mills, schools and places of public meeting were not closed and there was no evidence that persons frequenting such places or following any particular occupation were specially attacked.

The indications are more that the germs are present in persons' throats without doing them any harm, until certain favourable conditions arise, one of these being an influenza-like catarrh.

Although most of the cases occurred amongst the poorer classes, some rich persons were also affected.

There was a marked predominance amongst young adult males.

[It is not at all clear on what evidence the authors base their somewhat unusual and apparently-contradictory conclusions regarding the ætiology of the disease.—EDITOR, I.M.G.]

- (b) Necrotizing nephroses occurring in acute chemical poisoning (e.g., mercury).
- (c) Amyloid nephrosis as a part of a generalized amyloid disease.
- (d) Nephrotic changes occurring in the definitely inflammatory group of Bright's disease.
- (e) Pregnancy nephrosis.

The nephrotic syndrome is characterized by slight anaemia, marked oedema, copious albuminuria, good kidney function, absence of haematuria, normal or low blood pressure, no retinal changes, markedly reduced blood proteins, reversed albumin-globulin ratio, normal blood urea, high blood cholesterol, doubly-refractile lipoids in urine, and large white kidneys showing degenerative changes but with no fibrosis.

The essential pathology is a degenerative change in the tubules (and to some extent in glomeruli too) and deposit of lipid material. Some replacement fibrosis may occur and Vollhard has even described a nephrotic contracted kidney. Damage to the kidney results in copious albuminuria and it has been definitely shown by bleeding animals that nephrotic oedema and hyper-cholesterolaemia are due to depleted blood proteins. Blum and Caulaert have shown that oedema is due to the retention of sodium ions, and that ingestion of sodium should be restricted in these cases.

Larval, necrotizing and amyloid nephroses are often met with. Cases of chronic nephritis with low blood pressure and good kidney function were commonly observed in the wards of the King George's Hospital. Were these nephrotic syndromes of the primary nephrosis type or did they only denote secondary nephrotic changes in chronic Bright's disease? In order to get some insight into these problems I made observations on the chemical and biochemical features of 25 cases, and consulted the old records of 75 cases of nephritis.

Analysis.—I found that 70 per cent of the cases occurred between the ages of 20 to 40 years, and that 90 per cent of them were males. The outstanding clinical features were pallor and oedema. Malaria, ankylostomiasis and dysentery generally preceded an insidious onset. About 50 per cent of the cases had a normal blood pressure. Oliguria was present in all cases. Hyaline and granular casts were generally present. Though red blood cells were present in some of the urines, frank haematuria was neither observed nor was there any history of it.

The serum had a milky appearance in 40 per cent, probably due to the presence of a lipid-globulin compound. The serum proteins were diminished from 20 to 50 per cent. The albumin-globulin ratio was reversed in 40 per cent of cases. The serum chlorides were increased from 5 to 20 per cent. The serum cholesterol was increased in 70 per cent of the cases; this varied from 180 to 350 mgms. per 100 c.cm., but in one case it rose up to 900 mgms. Blood urea

was normal in 50 per cent. Kidney function was good in 25 per cent when judged by the specific gravity test, but in 35 per cent when judged by the urea concentration test.

A vigorous treatment with saline purgatives, alkaline diuretics, a salt-free diet and other physical measures usually reduced the weight by several stone, and the patients were apparently cured after a few weeks' treatment. As judged by the urea concentration test their kidney function did not improve and the relieved patients were very likely to revert back to their original condition. Only 17 post-mortem reports on nephritis cases were available and all showed signs of chronic inflammation.

Discussion.—The above observations showed that, though a complete picture of the nephrotic syndrome was not observed, partially nephrotic pictures are quite common and practically constitute the predominant type. Cases which at first sight presented a picture of chronic nephrosis invariably turned out on closer examination to be cases of chronic glomerulonephritis in which secondary nephrotic changes had set in. Sometimes, it must be admitted, it is impossible to distinguish between chronic nephrosis and nephrotic type of glomerulonephritis by clinical and biochemical tests. Very often only a microscopic examination of the kidney section revealed the true inflammatory nature of the disease which during life was thought to be of the degenerative type. That is why some writers doubt the very existence of a primary nephrotic condition. However, it is safe to say that primary, chronic or lipid nephrosis is as rare here as it is in Europe and in other countries.

As regards the aetiology of chronic nephrosis it is veiled in obscurity in a large proportion of cases. Some are said to be due to chronic infections. The predominance of nephrotic changes in Indians is probably due to the fact that nephritis in the large majority of cases is of insidious onset; and as a history of malaria, dysentery and ankylostomiasis preceding the onset of the disease is present in most of them, it is quite probable that their toxins may start, not only a chronic inflammation but also, concomitant degenerative changes in the kidneys.

Pregnancy nephrosis.—Toxaemias of pregnancy are quite common in Indians and do not differ in any particular way from those observed in other countries. 'Pregnancy nephrosis', as Cruickshank puts it, 'is seldom seen in pure form, however, being frequently accompanied by acute, sub-acute, or chronic nephritis'. But according to Fishberg 'certain clinical characteristics, notably the frequently extreme hypertension, separate it distinctly from the picture of nephroses as encountered in the non-pregnant state, so that it seems more judicious to retain for the present the non-committal term "kidney of pregnancy"'.

CLINICAL EVIDENCE OF RHEUMATIC FEVER IN THE PUNJAB

By KHUSHWANT LAL WIG, M.B., B.S. (Punjab)
M.R.C.P. (Lond.), D.T.M. & H. (Lond.)

Medical Outpatient Department, Mayo Hospital
Lahore

THE existence of rheumatic fever in the tropics has always been a disputed point. Its prevalence even in a sub-tropical climate like that of the Punjab has been looked upon with suspicion. Hughes and Yusuf (1930 and 1931) have presented some evidence in support

(Continued from previous page)

The kidney of pregnancy shows changes of degenerative type only. Though these have been attributed to toxæmia of pregnancy the actual existence of a toxin in pregnancy has not been proved. Volhard's angiospastic view seems to explain the facts better. According to him the kidney changes are purely of ischæmic degeneration—a local manifestation of a generalized angiospasm. The recent studies of Hoffman and Anselmino in the endocrine changes in pregnancy give a clue to the cause of this angiospasm. They have shown that in the last months of pregnancy there is a hypersecretion of the posterior lobe of the pituitary and especially of the oxytocic principle; but in cases of toxæmia of pregnancy vasopressine constitutes most of the pituitary secretion, and it naturally leads to an angiospastic condition. Even an eclamptic condition has been produced in animals by injection of strong doses of vasopressine.

The appearance of œdema in this condition is also explainable in terms of pituitary disturbance. The temporary hyperpituitarism leads to a retention of water and consequent œdema. Diabetes insipidus is a manifestation of the hypo-disturbance of the same water-controlling mechanism as conceived by Elwyn. In cases which are associated with glomerulonephritis the œdema may have a nephrotic or rarely nephritic element too.

Summary

Classification, the main characteristics, and a brief pathology of nephrosis is given. The author's experience has been summarized. Though partially nephrotic pictures in cases of chronic glomerulonephritis are quite common, primary nephrosis was not observed. A plausible hypothesis for pregnancy nephrosis has been discussed.

of the existence of rheumatic fever in the Punjab. They came to the conclusion that lesions of the heart, especially those of the mitral valve, often bear an ætiological relationship to a disease which in certain respects resembles the rheumatic fever of temperate climates. They described this disease to be a subacute affection of the various joints involving almost all the joints of the body with slight febrile disturbances though in some cases the disease may be more acute.

In the latter part of 1932, a controversy was carried on in the *British Medical Journal* in which the existence of rheumatic fever in the tropics and particularly in the Punjab was disputed. It was contended that, as mitral disease and chorea were rare diseases in the tropics, the diagnosis of the reported cases of rheumatic fever was questionable. Colonel Keates with his 25 years' experience in the Punjab maintained that rheumatic fever was practically non-existent among the indigenous population. He saw only 3 or 4 cases in 25 years and those only in town people. He never saw a case of primary disease of the mitral valve. Aortic disease due to syphilis in his opinion was quite common. He never saw an inflamed mitral valve in 600 post-mortem examinations done at Amritsar, though diseased aortic valves were commonly seen.

Colonel Hughes who took part in that correspondence was, however, of the opposite opinion. He based his conclusions on his experience in the Mayo Hospital. In his opinion rheumatic fever was by no means uncommon among the indigenous population of the province, and mitral disease was a frequent result of rheumatic infection. The arthritic manifestations in his opinion were usually subacute or mild, although typical rheumatic fever sometimes occurred. His enquiries from the Mayo Hospital pathologist gave him the information that mitral disease had been met with 7 times in 200 consecutive necropsies.

My attention to this subject was aroused by a case which I saw when posted at a dispensary in Attock district in 1932. A boy aged ten was brought to the outpatients' department suffering from pains in the limbs occasionally for the past 3 months or so and an occasional rise of temperature up to 99°F. or 100°F. The child was anæmic and weak. The heart seemed to be quite normal at this stage. He was put on salicylates and the pains stopped. The parents discontinued the treatment and the pains and other symptoms reappeared. The child was brought to the outpatients' department off and on for 2 months. Then on routine examination of the heart I noticed that the first sound was not quite clear. I advised admission of the boy into the hospital, but the parents refused to get him admitted and so the child was treated as an outpatient. A few days afterwards, however, the child began to get a high temperature and various joints got swollen.

At this stage they consented to allow the child to be admitted to hospital. The temperature now ranged between 102°F. to 103°F. and was of the continuous type. The apex beat became diffuse and tumultuous. The first sound became rough and a systolic murmur appeared in the mitral area. The second pulmonary sound became accentuated and sharp. Subcutaneous nodules, two on the forehead and one on the hand, also appeared. The child was put on high doses of salicylates. The swellings and pains in the joints subsided but the temperature, though it came down a little, was not completely controlled. The child remained in the hospital for about 2 weeks, but as there was no marked improvement he was taken away against my advice and died about a month afterwards.

Since the beginning of 1934 I have been collecting cases of rheumatic infection from the medical outpatient department of the Mayo

Hospital. Thirty cases in all have been recorded. They are by no means all the cases of rheumatic infection that attended the medical outpatient department during this period, as there must have been many others attended to by the other physicians. The histories taken included the symptoms which the patient came suffering from, the clinical examination, family history, the status of the patient and the locality from which he came. No electrocardiographic or x-ray examinations could be done as the cases recorded are from the outpatients' department.

Out of these thirty cases recorded, there were ten of simple articular rheumatism, fifteen showed an involvement of the mitral valve, and five patients were suffering from chorea.

Tables I, II and III show an analysis of the cases belonging to these three groups:—

TABLE I
Simple articular cases

Serial number	Religion and sex	Age in years	Important symptoms	Duration of illness	Type of disease
1	M. F.	9	High fever, acute pains and swelling of different joints. One subcutaneous nodule.	7 days.	Acute rheumatic fever.
2	S. M.	15	Fleeting pains in the joints off and on.	2 years.	Pains due to rheumatic infection.
3	M. M.	9	Pains in different joints. An occasional swelling of the ankles with slight fever.	2 months.	Rheumatic fever, subacute.
4	M. M.	16	High fever. Fleeting pains and swelling of different joints. Had a similar trouble 6 months previously.	1 month.	Acute rheumatic fever.
5	M. M.	16	Pains in the various joints and limbs. An occasional slight rise of temperature. Recurrent attacks of sore throat.	..	Pains due to rheumatic infection.
6	M. M.	10	Pains in the joints and extremities. Recurrent sore throat.	3 years.	Pains due to rheumatic infection.
7	M. M.	10	Pain and swelling of knees and then wrists. Temperature 100°F. Sore throat.	15 days.	Rheumatic fever, subacute.
8	M. M.	20	Pains and swelling of different joints. High temperature for 10 days and then low fever. History of sore throat.	1 month.	Do.
9	H. M.	17	Pains and swelling of different joints. High fever for 10 days and then a low fever.	1 month.	Do.
10	M. M.	6	Pains in various joints. Swelling of both ankles. Daily fever 100°F. Enlarged tonsils.	1 month.	Do.

TABLE II
Cases showing an involvement of the heart

Serial number	Religion and sex	Age in years	Previous history	Type of cardiac lesion
1	M. F.	15	Pains and swelling of joints one year ago.	Mitral stenosis.
2	M. M.	25	Pains and swelling of various joints since childhood.	Do.
3	H. M.	40	Pains and swelling of different joints at the age of ten and again at the age of thirty.	Auricular fibrillation following mitral stenosis.
4	H. F.	7	Pains and swelling in different joints of 4 months' duration.	Double mitral disease.
5	H. M.	14	Pains in the limbs and joints of 5 years' duration.	Mitral stenosis.
6	H. M.	12	Fever, pain and swelling of the joints—15 days' duration.	Early rheumatic endocarditis of the mitral valve.
7	M. M.	22	Floating pains in different joints—5 years' duration.	Aortic regurgitation with mitral stenosis.
8	M. F.	25	Pains and swelling of joints off and on for the last 7 years.	Do.
9	M. F.	18	Recurrent attacks of pain in joints—8 years' duration.	Paroxysmal attack of auricular fibrillation due to mitral stenosis.
10	M. F.	45	Attacks of pain and swelling of joints since childhood.	Double mitral disease.
11	M. F.	24	Pains in the various joints and low fever 2 years ago.	Aortic regurgitation and mitral stenosis.
12	M. F.	25	Pains in different joints with occasional swelling of shoulder—duration one year.	Double mitral disease.
13	M. F.	38	Painful swelling of the joints at the age of 16 and again at the age of 22.	Mitral stenosis.
14	S. M.	11	Acute rheumatic fever 5 years ago.	Double mitral disease.
15	S. M.	40	Fever, pain and swelling of different joints—duration one month.	An early lesion of mitral valve.

TABLE III
Cases of chorea

Serial number	Religion and sex	Age in years	Previous history	Present condition
1	M. M.	7	Fever with pains and swelling of joints four months previously.	Irregular purposeless movements, inco-ordination and weakness of musculature.
2	C. M.	9	Pains in different joints three months previously.	Irregular movements, ataxia of movements and lack of power in the limbs.
3	M. F.	11	Pains in knees and extremities two years previously.	Irregular movements, ataxia and weakness of musculature.
4	C. F.	12	No history of rheumatic infection of the joints.	Irregular movements, ataxia and weakness of musculature.
5	M. M.	11	Fever with pain and swelling of different joints one month previously.	Irregular movements, weakness of muscles and inco-ordination of movements.

It will be seen from the tables that the cases of simple articular rheumatic infection were mostly subacute in nature. All the fifteen cases in which the heart was involved showed a lesion of the mitral valve. Three of these mitral cases showed in addition a diseased aortic valve as well. All these heart cases gave a clear history of a previous attack of subacute or acute affection of the joints. There were five cases of chorea in the series. Four of them gave a definite history of having previously suffered from articular rheumatism. The fifth case may be taken as one in which chorea was the first symptom of rheumatic infection. Only one case in the series gave a history of rheumatic infection in other members of the family.

The cases came from the villages as well as the congested areas of the towns. Most of them were poor but that may be because the hospital attending population is mostly poor. The rheumatic infection of the joints occurred in a great majority when they were still young.

The following four case histories, one that of a case of acute rheumatic fever, the second that of a case of subacute rheumatic infection of the joints, the third that of a case showing cardiac involvement and the fourth that of a case of chorea, are described below in detail as typical examples of the cases belonging to the different groups:

Case 1.—H., a Mohammedan female child, aged 9 years, came in with high fever, temperature 103°F., duration 7 days, with acute pains in the various joints of a shifting nature and swelling of the wrists and ankles. There was one subcutaneous nodule behind the right elbow which was very painful. The heart was normal. The pulse rate was 120. There was no history of sore throat. One sister and her mother suffered from occasional pains in various joints. The patient came from a congested quarter of Lahore. Her father was poor.

Diagnosis.—Acute rheumatic fever with one subcutaneous nodule.

Case 2.—M. A., a Mohammedan male, 6 years of age, came in complaining of pains in the various joints of the body with a swelling of both the ankles and a daily rise of temperature every evening up to about 100°F. The complaint was of one month's duration. The child was anæmic. Pulse rate was 100. Tonsils were enlarged and congested. The size of the heart and its sounds were normal.

There was no family history of rheumatic fever. The child came from a congested quarter of Lahore and was of poor means.

Diagnosis.—rheumatic fever.

Case 3.—S. S., a Sikh male child, aged 11 years, complained of dyspnoea and palpitation of 5 years' duration which started after an attack of acute fever in which nearly all the joints got swollen and painful one after another. Since then he has been getting slight pains and swelling of different joints occasionally. The feet were œdematous and the liver enlarged. The apex beat was beyond the nipple line and diffuse in character. The first sound was roughened and was followed by a systolic murmur which was being conducted up to the angle of scapula. The second sound was accentuated and sharp. There was no family history of rheumatic fever. The child was brought from Rawalpindi and belonged to a well-to-do family.

Diagnosis.—Mitral disease of rheumatic origin.

A SIMPLE TECHNIQUE FOR THE DETECTION OF SMALL TRACES OF CHLOROFORM IN VACCINE LYMPH

By K. S. SHAH, D.Sc., D.P.H.

Officiating Superintendent, Punjab Vaccine Institute

VACCINE lymph is a preparation of the substance obtained from the vesicles produced on the skin of healthy animals by inoculation of vaccinia virus. When collected from the vaccineifers, lymph is always found to be contaminated with extraneous micro-organisms, which should either be eliminated or considerably reduced before it can be issued for human vaccination.

The procedure necessary to bring the contents of bacteria and other visible micro-organisms within the prescribed limit varies in

(Continued from previous column)

Case 4.—K. Z., a Mohammedan male, aged 7 years, came to the medical outdoor department showing irregular movements of all parts of the body with marked weakness of the limbs and inco-ordination. The patient had twice severely injured himself by sustaining falls. The arms when outstretched showed flexion at the wrist and extension at the fingers. When asked to protrude his tongue and then take it back, he would do it with a sudden jerk. The child was anæmic and looked emaciated. Pulse rate was 100 per minute. The heart was normal. Four months previously the child had suffered from an attack of fever in which he suffered from pains in all the joints and swelling of both wrists and ankles. The attack lasted for about a month. The child was treated for chorea on the usual lines with 5 grains of aspirin-given twice daily. The child showed a gradual improvement and in about one month made a complete recovery so far as the movements were concerned. The pains did not recur and the child showed a gradual improvement in his physical condition as well. The other brothers and sisters had no rheumatic history. The child lived in a congested area of Lahore. The father was a barber and had poor means of living.

Diagnosis.—Chorea with a rheumatic history.

Summary

1. Thirty cases of rheumatic infection have been studied.
2. The disease exists in all its forms, i.e., articular, cardiac and chorea.
3. The articular form of the disease is mostly subacute in nature.

For the above work I am deeply indebted to Lieutenant-Colonel D. H. Rai, I.M.S., Professor of Pharmacology, King Edward Medical College, Lahore. The work was taken up at his suggestion and was throughout done under his kind guidance.

different countries. In Great Britain this limit is 5,000 organisms per c.cm. (*vide* Statutory Rules and Orders, 1931, No. 633, Therapeutic Substances, page 21), and is brought about by subjecting the lymph to a temperature of 15°C . for one week.

In the Anti-Toxin and Vaccine Laboratory Department of Public Health, Massachusetts, U. S. A., lymph is incubated at 37°C . for less than two hours, as exposure to heat brings about a rapid fall in the bacterial count.

In the Punjab Vaccine Institute, the same object is attained by passage of chloroform vapour through the lymph. As continued presence of chloroform in the lymph is detrimental to its potency, it is removed by passing filtered air through it after 24 hours. When chloroform can no longer be smelt from the 'exit tube' lymph is considered to be free of it. The 'smell test' has so far given satisfactory results. It is, however, open to certain objections. In the first place, the personal factor plays a great part, some persons having a more acute sense of smell than others. Secondly, very minute traces of chloroform cannot be detected by this method.

A simple technique has, therefore, been evolved, and is highly satisfactory. It is based on two factors:—

(1) Chloroform is soluble in alcohol.

(2) It gives a blue colour when brought in contact with a solution of β naphthol in strong solution of potassium hydroxide.

Procedure.—Take about 5 c.cm. of absolute alcohol in a glass test-tube.

2. Pass a current of air (supposed to contain traces of chloroform) through it for a few minutes.

3. Add about 2 c.cm. of a solution of β naphthol in a strong solution of potassium hydroxide.

4. Heat it to 50°C . in a water bath.

5. If chloroform is present a blue or greenish-blue colour will develop.

This method will be of considerable help in determining the time lymph should be subjected to aeration after chloroforming.

[*Note.*—We do not know whether this test has been applied hitherto for detecting traces of chloroform in vaccine lymph; the Guareschi-Lustgarten reaction was, however, described as long ago as 1872 (*Ber. d. deutsch. chem., Ges.*, V, 1053).—EDITOR, I.M.G.]

A Mirror of Hospital Practice

A CASE OF GUINEA-WORM INFECTION

By K. L. BASU MALLIK, M.B.

Medical Officer, Ludlow Jute Company Limited,
Chackasi, Howrah District

C. N., a jute mill coolie, aged about 25 years, came to get his foot dressed with a worm sticking out to the length of about ten inches.

History.—He came to work in the Ludlow Jute Mills at Chengail about five months ago from his native place, Kumili in Vizagapatam. Two weeks ago

he had a painful blister below the right ankle which burst and refused to heal up. Then he noticed the white string-like worm emerging and came to the

dispensary for treatment. Two years ago two similar worms came out of his right leg below the knee joint and two scars are present indicating the sites. The worm was tied to a piece of matchstick and wound round it. The diagnosis was confirmed by Dr. Sundar Rao of the Calcutta School of Tropical Medicine.

The worm was being daily pulled out bit by bit for about five or six days, and during this time the patient suffered from no inconvenience such as fever or allergic manifestation and continued at his work. One day during the absence of the writer the dresser tore off the extruded portion of the worm and subsequently an area radiating from one lip of the initial ulcer became swollen and very tender. A director was passed and an incision was made to let the pus out. Four days later the end of the worm was visible in the wound and on slight and careful pulling the whole of the remaining portion came out measuring six inches. The end was tapering and the characteristic hook-like tail extremity was visible. This torn portion appeared to be alive and moved in water. After the last portion was out the wound began to clean up and it healed uneventfully in about eighteen days.

[*Note.*—Although this case is reported from Bengal the source of infection is obviously his native district in Vizagapatam. No authentic case of guinea-worm infection originating in Bengal has ever been recorded.—EDITOR, I.M.G.]

A CASE OF MALIGNANT TUMOUR

By J. C. GHOSH, M.B.

Calcutta

J. N. P., a Hindu male, aged about 60, a native of Murshidabad district, came to me on

the 3rd January, 1935, with the following complaints:—

- (a) A swelling immediately below the right ear which has advanced on to the face as well as posteriorly, and also into the neck.
- (b) Pain over the swelling, which exacerbates at times and radiates to the back of the head.
- (c) Lacrimation from the right eye.
- (d) Dribbling of saliva from the right side of the mouth.
- (e) Slight fever.

The patient says that the swelling has been present for six and a half months and it has gradually developed to its present size. He suffers from pain especially when he lies on the right side. He feels comfortable, when he bends his head and neck on the affected side. He has had epiphora and dribbling of saliva for about a month. When he attempts to drink water or other fluid part of it escapes from the right side of the mouth. He also has partial difficulty in opening his mouth.

He gives a history of penile sores and thereafter eruptions on the body, in youth.

Family history.—Nothing bearing on the present illness.

Physical examination.—The swelling:—(1) Situation:—below the right ear, extending forwards to about the anterior border of the ramus of the mandible and posteriorly over the sterno-mastoid to the adjacent portion of the posterior triangle and below to the anterior triangle to the level of the hyoid bone. The swelling has, moreover, masked the angle of the mandible and the mastoid process.

(2) The superjacent skin is adherent to the swelling. Recently the portion of the skin behind and below the external ear has turned 'eczematous'.

(3) The swelling is very hard and fixed.

Face:—The right side of the face, as a whole, appears to be swollen and sagging downwards. It shows:—

- (a) Smooth forehead—right half—there being no wrinkle formation.
- (b) Right eye appears to be narrower than the left. Right eyelids close imperfectly and are oedematous.
- (c) The angle of the mouth is drawn upwards and to the left; this retraction becomes more prominent on attempting to set the teeth upon one another.
- (d) The tongue deviates to the affected side.

These physical signs together with epiphora and dribbling of saliva and escape of fluid from the mouth indicate facial paralysis.

Other findings

Right trapezius.—The cervical portion (the part between the occiput and the acromion) is atrophic, the natural slope between the neck and the shoulder has become less definite and has been rather converted into a hollow, raising of the right upper arm above the shoulder is affected, and the patient feels discomfort in maintaining extension of the head.

In the right-posterior triangle, there is a well-marked ridge-like elevation, ascending from the clavicle upwards and medial-wards; this is presumably the levator angulae scapulae. The prominence of this muscle is most probably due to the increased action forced on it in keeping up the point of the shoulder without the assistance of the trapezius.

Right sterno-mastoid.—The upper half is masked by the swelling; the lower half cannot be properly felt. Again there is want of prominence due to the contraction of the muscle. The rotation of the neck to the opposite side and the bending of the head to the same side is however not affected, but the movements are not free.

No other abnormalities except slight prolongation of breath sounds with some harshness and a few crepitations on both sides.

Comment on the case.—The swelling is in the situation of the right parotid gland. Its rapid growth in six months, its extreme hardness, immobility, adhesion and apparent involvement of the skin and the resulting facial paralysis all suggest that it is a malignant growth of the parotid gland.

An interesting point in this case is that in addition to facial paralysis, there is also present atrophy of the trapezius and sterno-mastoid muscles on the same side. The atrophy of these muscles suggests that the growth has exerted pressure on the right spinal accessory nerve and most probably compression paralysis is present.

The lower part of this nerve passes through the neck along a line drawn from the angle of the mandible to the mid-point of the posterior border of the sterno-mastoid. It pierces the sterno-mastoid about the level of the angle of the mandible five centimetres from the mastoid process. The growth of the parotid has encroached into the neck beyond this line. So,

it is natural to assume that it has compressed the nerve.

The following quotation from 'The Elements of Surgical Diagnosis' by Dr. Gould supports this contention. 'Injury of the spinal accessory nerve shows itself in paralysis of the sterno-mastoid and of the cervical part of the trapezius'.

VIPER SNAKE BITE: TREATMENT AND RECOVERY

By C. R. CHETTI

Bassein, Burma

A HINDU male, aged eighteen, a gardener, was bitten by a yellow-spotted viper at 3 p.m. on the 2nd January, 1932, about three inches below the left knee on the outer aspect of the leg.

History.—He was bitten while cutting grass and was brought to me at about 3-30 p.m.

Condition on admission.—The patient was unconscious, pulse feeble, respirations hurried and 48 per minute, body and extremities fairly warm and perspiring freely. Pupils—dilated.

Treatment adopted.—A ligature was immediately applied above the knee, a few scarifications were made over the bite and potassium permanganate crystals dissolved in a little water was rubbed in and covered by a bandage. Twenty cubic centimetres of antivenin were injected into each median basilic vein. About five minutes after the injection the man recovered consciousness and when questioned he said he did not remember anything after he was bitten by a snake while he was cutting grass in the garden. Apprehending hæmorrhage, I gave him 40 grains of calcium chloride dissolved in two ounces of water internally. About half an hour after the injection his pulse improved and he was able to walk. After keeping him for about two hours he was sent back to his house with instructions to report his condition to me the same evening. A messenger came the same evening and informed me that the patient was passing blood in the stools. The calcium chloride mixture was continued thrice daily and after two days the mæna stopped. The wound was dressed for four days by which time the man had completely recovered.

A CASE OF MELANOMA OF RECTUM

By S. R. INGLE

Sub-Charge, Civil Hospital, Jalgaon E. K.

Case report

A HINDU male, aged about 45, was admitted to this hospital on 6th February, 1935, with the history that he had been passing loose motions, containing mucus and blood with tenesmus and prolapse for about a month and a half. Prior to this, he was enjoying good health.

On admission, he was found to be weak and anæmic from loss of blood and sleeplessness caused by constant pain. Physical examination of the chest and abdomen was negative. No enlarged glands could be detected. An examination of the rectum revealed a soft, nodular, pedunculated, easily bleeding, painful and tender mass the size of a small orange, springing from the left lateral and posterior wall of the rectum. A similar but a smaller growth could also be palpated just below it. A clinical diagnosis of papilloma was made and the patient was operated on by the civil surgeon on 20th February, 1935, and the tumours were excised. His convalescence was uneventful. He was discharged

'cured' on 2nd March. The Director, Haffkine Institute, Bombay, to whom the growth had been sent for a pathological examination, reported it to be a melanoma.

The rarity of such a condition has prompted the publication of this note.

I can find no reference in the available literature to the presence of such a tumour in the rectum. These neoplasms generally grow from the pigmented areas of the body such as the rete mucosum of the skin, pigmented moles, or the choroid of the eye. Its presence in the rectum may, however, be explained by the fact that melanin is formed in relation to the cells and stroma of certain epithelial tumours, giving rise to melanotic cancer.

I am grateful to the civil surgeon for his kind permission to publish these notes.

A CASE OF SEVERE BLEEDING AFTER TOOTH EXTRACTION*

By M. N. SIRSAT, L.C.P. & S.

Medical Officer in charge, Dispensary Mokhada, Thana District

A MOHAMMEDAN aged 35 came to Mokhada dispensary for extraction of teeth on 8th February, 1935. Three teeth were extracted at one sitting and there was unusual bleeding from the socket of the upper right second molar; this was checked with an iodine swab. Early on the 10th of February profuse bleeding started from the same socket and the patient came to the dispensary at about 3 a.m. for admission.

Treatment.—On admission a gargle of potassium permanganate was given and the tooth socket packed with gauze soaked in iodine. This was ineffective so an adrenaline pack was tried and calcium lactate given every half hour but the bleeding continued. A turpentine pack was now tried but without apparent effect as it became soaked in blood and had to be renewed about every half hour. At 5-30 a.m. an injection of morphia and atropine was administered without effect and at 6 o'clock he was given a hypodermic injection of 5 c.cm. of horse serum and the bleeding stopped. The patient slept for about five hours and was allowed some tea to drink, which started the bleeding again.

A pack soaked in tincture of perchloride of iron was now tried but it had no effect, so turpentine was again used and a second injection of 5 c.cm. of horse serum was given. This controlled the bleeding and there was no recurrence until 9 a.m. on the 12th about one hour after the pack was removed from the socket and was not renewed. A fresh pack of perchloride of iron was tried and a gargle of hydrogen peroxide used but without effect, so the socket was again packed with a turpentine swab.

About a year previously I had had a good result with emetine in controlling bleeding from the nose and gums in a case of snake bite, so I tried an injection of gr. $\frac{1}{2}$ of emetine hydrochloride in this case and the bleeding stopped at once.

The next morning the pack was again removed and half an hour later there was a recurrence of the bleeding. The socket was again packed with turpentine-soaked gauze and a second injection of emetine given, and after some time the bleeding stopped and did not recur.

Although the evidence that emetine controlled the bleeding in this case is inconclusive its effect is certainly suggestive.

MAY

SPLENIC ANÆMIA AND TREATMENT BY SPLENECTOMY

THERE are probably few clinical conditions that are a greater source of annoyance to the officer in charge of a general medical outpatient department in Bengal than that in which there is considerable enlargement of the spleen, definite anæmia, slight fever and a general feeling of malaise; such cases often form a comparatively large proportion of the total attendance. Kala-azar, chronic malaria and leucæmia can usually be excluded without much difficulty; the first by means of the formaldehyde test, the second by examination of a blood film for malaria parasites or by a therapeutic test with the cinchona alkaloids, and the third also by a blood film examination. After exclusion of these three common causes of splenic enlargement there is still a considerable residue. By more elaborate laboratory examination, such as a Wassermann reaction, it will be possible to pare down this group still further, but many cases will still remain and as they seldom improve on ordinary medical treatment they tend to accumulate amongst the 'old cases'.

It is a time-honoured maxim, which practitioners in the five continents have always followed, that in all cases a diagnosis must be made, so the two constant symptoms in this group of cases have been used to coin the word 'splenic anæmia'; if even there was a good answer to the question 'When is a diagnosis not a diagnosis?' it is 'When it is splenic anæmia'. This fact has been fully recognized and expressed by such phrases as 'incomplete knowledge is essential to the diagnosis' (Mayo) and 'if we know the cause of splenic anæmia, it is no longer a case of *splenic anæmia*' (Moynihan). The name 'Banti's disease' is applied to a slightly more definite symptom complex, but still even this has no established ætiology; Banti's original suggestion that it was due to a toxin that had a specific action on the spleen seems to have been of the nature of a guess and has never received any experimental support.

By a process of not very deep reasoning the term 'tropical splenomegaly' has been applied to conditions of splenic enlargement of unknown ætiology that occur in the tropics, and for the condition as it is encountered in Bengal the term 'Bengal splenomegaly' has been applied. By a similar process of argument the cases of enlarged spleen that occur in the Punjab might very well, and probably have been, referred to as 'Punjab splenomegaly'. It might be said that such multiplication of names is ridiculous,

but we do not agree; both Bengal and the Punjab are tropical (or sub-tropical) countries but in some ways their climates are as different from one another as either is from the climate in Italy, for example; it is therefore possible that the ætiology of the splenic enlargements in these two countries is different, and it is as well to maintain the distinction until such time as the conditions are shown to be the same.

The splenomegaly that is encountered in Bengal shares many of the characteristics of Banti's disease; it is chronic, it is commonest in early adult life, it is primarily a splenic enlargement that is usually followed by enlargement and finally cirrhosis of the liver, and ascites; hæmorrhages from mucous membranes occur but the profuse gastro-intestinal hæmorrhages that are described in Banti's disease do not appear to be common. There is a marked anæmia but this is seldom extreme and does not seem to be very definitely progressive, the anæmia is said to be of the microcytic hypochromic type, but we have not always found this to be the case and it is certainly not markedly hypochromic, there is always a granulocytopenia, urobilin is present in the urine in excess and the van den Bergh, direct delayed, reaction is often positive.

Histologically, there is considerable disorganization of the spleen structure, the malpighian follicles are reduced and eventually almost entirely replaced, there is considerable endothelial cell proliferation, some increase of the reticular fibres and thickening of the trabeculae and capsule; the thrombosis of the splenic vein that is described in cases of Banti's disease in Europe has not been noted, nor has the dilatation of the œsophageal and gastric veins.

The feature that links the splenomegaly of Bengal with Banti's disease is the complete failure of all forms of medicinal treatment to stay the course of the disease; after many years of ill-health the patient usually dies of some intercurrent infection. Surgical treatment, that is to say, removal of the spleen appears to be the only form of treatment that offers any hope. This has for some years been the recognized treatment for Banti's disease in temperate climates and on the whole the results have been fairly satisfactory; a 50 per cent cure rate is claimed. In the tropics not only the patient's prejudice against surgical interference but also a deep-rooted feeling on the part of the medical profession in these countries that the spleen is more important to the residents in the tropics than it is to those who live in temperate climates has to be overcome. This is partly due to the fact that in certain diseases, for example, kala-azar, removal of the spleen has had very unsatisfactory results. Those who have followed the experimental work on malaria in monkeys will, we feel sure, hesitate before allowing their spleens to be removed lightly. It has been shown that the monkey,

Silenus irus, habitually harbours a plasmodium that in the ordinary course of events seems to cause him little inconvenience, but that if his spleen is removed the infection fulminates and is frequently fatal. There is, of course, a difference between the reactions to infection of *Silenus irus* and of *Homo sapiens*, but the analogy is too close to make one feel entirely happy about the chances of survival for any considerable time in a tropical country, without a spleen.

In Europe this question of the splenectomized has been studied fairly thoroughly; recently in Switzerland, Renfer followed up 15 persons who had had their spleens removed following accidents; the average time interval since the removal of the spleen was about 10 years. Fourteen of the fifteen were still alive; three had distinctly impaired health, but it was difficult to attribute their conditions to loss of their spleens as other organs had been damaged at the time of their accidents. This investigation was made from the point of view of accident indemnity, and the conclusion arrived at was that loss of spleen *per se* did not constitute grounds for indemnity.

There are two papers in this number of the *Gazette* that deal with the surgery of the spleen. The authors of these papers report 10 and 19 cases respectively, in which splenectomy was performed; in the first series the spleens were removed for medical and in the second for surgical reasons. One death occurred in each series immediately following the operation; in view of the seriousness of the operation this must be considered a very satisfactory immediate result. However, the really important point is to know the after-history of these patients, and we sincerely hope that these writers will endeavour to keep in touch with their patients for some years. Colonel Palit, the author of the first of these two papers, is a surgeon, and had not the facilities for carrying out detailed medical investigation of his patients before and after operation, but from the blood counts he gives it appears that most of his cases could be classed as 'splenic anæmia', that is to say, they had definite but not profound anæmia, and a leucopenia that was most marked in the polymorphonuclear group. It is also apparent that the blood counts returned to normal after the patient had recovered from the operation.

These two papers indicate a considerable advance in the surgery of the spleen in India, and they also suggest that surgical removal of the spleen may be as safe an operation in India as it is in non-tropical countries. There is undoubtedly a very great opportunity for a combined surgical and medical investigation on this subject. The prognosis in these cases of 'splenic anæmia' is very poor; medicinal treatment seldom effects more than a temporary improvement, and, though the patients may not be acutely ill, they usually remain in a state of

subnormal health for a few years and then die of some intercurrent infection.

In our present state of knowledge we do not consider that it is justifiable to recommend indiscriminate removal of spleens for this whole group of cases, but the evidence at our disposal would certainly justify a clinical experiment on a large scale in cases in which other treatment has failed to produce either any improvement at all, or only temporary improvement. By this we do not mean to suggest that the patients should be left until they are *in extremis*, or even allowed to go on to the stage of liver cirrhosis and ascites, as this would scarcely give the surgical treatment a fair trial, but they should be placed under medical treatment for some months during which time a very careful watch is kept on their progress. Those cases in which improvement up to a stage can be effected but which tend to relapse directly this treatment is discontinued will probably prove to be the most suitable for surgical treatment, as in these cases intensive medicinal treatment can be given immediately preceding the operation, and the operation risk thus lowered very considerably. It is said that cases in which the platelets are reduced are the best subjects for operation; where the platelets are increased thrombosis is liable to occur.

In order to obtain the best research value from such an experiment, it would be essential to carry out very complete hæmatological examinations, before, during and after splenectomy, in order that the cases might be arranged into different groups, or their homogeneity established, as it is possible that in one class of case the operative treatment might be successful and in another unsuccessful, or even dangerous, a histological study of the spleens should be made, and, perhaps most important of all, the cases should be followed up for a number of years and some arrangements made for periodic re-examination.

BRITISH SPAS

How often does the doctor in this country advise his patient to take leave in Europe, and how seldom is this accompanied by any further advice as to where he should go and how he should spend his time for the greatest benefit to his health? If the patient's home is in Europe, he will naturally wish to go to some place near his home and as to how he shall spend his time he will usually have very fixed ideas on this subject which will vary according to his individual taste. This does not however absolve the doctor from the responsibility of giving sound advice, and also of impressing upon his patient the necessity for following it. If on the other hand the patient is an Indian, advice on this subject will almost certainly be sought and will probably be followed more readily.

Though after debilitating illnesses, such as malaria and dysentery, the voyage to England

will often enable the patient to regain his original health, there are other instances where the patient remains in an indifferent state of health, seeks only casual medical advice, and eventually returns after six months' leave in possibly an improved but at the same time a definitely subnormal condition, whereas two months of spa treatment under proper medical discipline would have made all the difference. In cases where the doctor has to consider the interests of the employer as well, he should in certain circumstances insist that the patient follows some sort of health regimen.

There are in Great Britain nearly four hundred inland or sea-side health resorts but there are only about sixteen spas where some form of organized medical treatment is carried out. This figure compares unfavourably with that of some of the other European countries, such as France and Germany, where there are, respectively, 83 and 58 recognized spas. However, there is not much advantage to the individual patient in this multiplicity, and it is usually possible from these sixteen British spas to choose at least one that will suit his particular requirements. Though there are spas in the south of England, such as Bath and Cheltenham, particularly suited to winter treatment, the 'tonic' spas, such as Harrogate or, further north, Bridge of Allan, are far more suited to the requirements of the majority of patients returning from the tropics and taking leave in the summer months than are the more sedative spas on the continent of Europe, where the climate is much warmer and is occasionally oppressively hot, and where one of the great advantages of climatic treatment, contrast, is lost. This of course does not apply to the Alpine spas, but in this case there is the danger that the contrast may be even too great.

It has for many decades been the fashion for doctors in England to order their patients to go 'abroad' without considering fully whether the patient's condition could not be treated as well in Great Britain, for there are some four or five British spas with quite remarkable properties, equal to if not better than any that

can be found in other countries. However, in recent years economic conditions have changed, foreign exchange rates have become unfavourable to the visitor from England, and British spas are coming into their own; their special advantages are being appreciated and they are being patronized far more than hitherto by the residents of other parts of the British Isles, and therefore they are being developed. Although of course the waters and the climate are the same, the facilities for special forms of treatment are being increased.

Another important point is that in other countries where there are large numbers of spas the advantage to that country that accrues from the attraction of a number of visitors has been fully appreciated and the national value of these health resorts has been recognized for a number of years; consequently the training of graduates in this special branch of medicine has been far more highly developed in these countries than it has in the past in England. Here the teaching in balneology and allied subjects has been to some extent neglected, but there are signs of a very distinct revival. Furthermore, with the formation of the British Health Resorts Association, scientific and accurate information on the subject of spa treatment in Great Britain is now much more easily obtained. All this has tended to increase the standard of treatment given at the British health resorts and spas.

Doctors in India have always recognized the special advantages of the British spas; this can be gathered from the high percentage of Indian residents that will be found amongst the visitors to any of these spas; but in the past they have often been discouraged from sending patients to the spas from lack of information and by the absence of specialization in the treatment of certain conditions. This cause of complaint is rapidly being removed, and there are now few conditions, amongst those to which spa treatment can be expected to do good, that cannot be treated as well at one of the sixteen British spas as they can at the spas in other countries.

THE TRANSMISSION OF KALA-AZAR IN INDIA*

By L. EVERARD NAPIER, M.R.C.S., L.R.C.P.
Calcutta School of Tropical Medicine, India

FIRST of all I should like to emphasize the geographical limitations of the title of this note, the transmission of kala-azar in India. Though it is very probable that when the whole story of the aetiology of the disease is told we shall find that there is the

closest correlation between the means by which it is transmitted in different parts of the world, at present, in view of certain apparent striking differences in its epidemiology in the various endemic foci, it is as well for workers who have investigated the disease in one endemic focus only to limit their conclusions to that area. For example, in the Mediterranean endemic areas kala-azar is a disease of infants, whereas in India it is rare in infants, the second and third quinquennial age groups show the highest incidence, and a large number of adults are affected. Admittedly, the more closely the disease is investigated in Europe, the greater is the number of adult cases encountered, and similarly in India, until the investigations were carried into the villages, it was looked upon mainly as a

* Being a paper read at the Ninth Congress of the Far Eastern Association of Tropical Medicine at Nanking on 4th October, 1934.

disease of adults and adolescents. However, no amount of close investigation will wash out the essential differences between the age distribution of the disease in these two endemic foci.

In the transmission of a disease there are so many factors involved that an essential difference in epidemiology does not necessarily mean difference in the mode of transmission; on the other hand, such differences in epidemiology do make differences in the mode of transmission in the various endemic areas a possibility that should not be ignored, and excuse one from the necessity of fitting the picture evolved in one country to conditions in another.

Between the epidemiology of kala-azar in China and in India there do not seem to be any *very* great differences. This remark is conditional, being based on first-hand knowledge of the disease in one country only, and in the other on information gained from the literature and in discussions with investigators from China, especially with my friends the late Dr. Young, Dr. Struthers and Dr. Smyley, so that such differences as have been noted may be apparent only, or on the other hand there may be more important disparities which my limited knowledge of conditions in China has led me to overlook. For example, Dr. Young did not find any evidence of epidemic incidence, nor of house incidence in the endemic areas; these are familiar features of the disease in India, and it is possible that recent investigations in China may have shown that they exist there also.

Let us turn to another aspect of the disease; the anatomical distribution of the causative organism seems to be different in the two countries. In early days in China Cochrane resorted to gland puncture as a means of diagnosis, whereas in India we have rarely found the parasite in lymphatic glands, either during life or *post mortem*. The histological studies of Meleney (1925) and others seem to indicate that submucous infection in the intestinal tract is far more common in China than in India, and recent clinical observations indicate that the same is true with regard to the respiratory submucosa. Cash and Hu (1927) were able to demonstrate leishmania in the skin in cases of kala-azar with considerable frequency, whereas we in India have always failed in cases of kala-azar, though in the post-kala-azar dermal lesions we can usually demonstrate the parasite histologically and always culturally. This may simply be a matter of technique, but other workers in India besides myself have failed to demonstrate the parasite histologically in the skin during the visceral stage of the infection. Culturally, of course, the parasite can be demonstrated, but it is impossible to exclude the peripheral blood as the source in this case. On the other hand post-kala-azar dermal lesions have not been demonstrated in China. Thus the histological and clinical observations would appear to be entirely contradictory.

I do not propose to discuss in detail the early investigations into the kala-azar transmission problem, but certain implications of your recent work in China have made me feel that a short reference to some of our early, sterile investigations might not be out of place. Since the conclusion of the Great War allowed us to turn our attention to such problems, there have been two major investigations into kala-azar in India, the enquiry at the Calcutta School of Tropical Medicine with which I have been associated for the last fourteen years, and the Kala-azar Commission under the Indian Research Fund Association which operated, mainly in Assam, for about seven years, from 1924-31; for the last three and a half years these two investigations have been in effect combined. I think I may say that, in the case of both these enquiries, the workers started with very open minds. Col. Christophers (now Sir Rickard) the director of the latter enquiry, who at that time enjoyed a world-wide reputation for his entomological investigations

and might therefore have been thought to be prejudiced in favour of insect transmission, spent the first six months or so after the formation of the commission exploring the possibilities of direct transmission, until our observations in Calcutta directed his attention to the sandfly. Again, in Calcutta I myself was very much impressed by the apparent association between insanitary conditions and kala-azar, and, whilst collecting data, which when analysed later showed that this association was more apparent than real and that I had probably been misled by a partial correlation, we carried out systematic examinations of the secretæ and excreta of our patients. We examined the urine, faeces, sputum and nasal mucus, with consistently negative results, except that we found from time to time suspicious bodies in the faeces which we believed were yeasts. Shortt (1923) obtained a positive culture from the urine of a kala-azar patient, but we (Napier and Das Gupta, 1923) found that, though a single drop of blood of a patient added to a catheter specimen of urine enabled us to recover a leishmania culture, we could never obtain this growth from a kala-azar patient's urine that was entirely free from albumin. Shortt and his colleagues on the Kala-azar Commission (1929) found undoubted leishmania bodies in the dysenteric stools of kala-azar patients, and more recently we have found leishmania in the nasal smear from a case of dermal leishmaniasis (Napier and Das Gupta, 1930). Against these few positive observations there is a great number of entirely negative ones that have never been fully reported. None of these findings is, in my opinion, very important, as, though they demonstrate means by which the parasite *can* leave the body, the conditions were in each case exceptional and they do not constitute any regular channel of escape. Further, as neither the development, nor even the survival, of the parasite under conditions obtainable in Nature has been demonstrated, immediate transference of the virus to the second host would appear to be essential if infection is to take place. Mention of these findings has only been made to emphasize the fact that, whilst the sandfly has undoubtedly received the lion's share of the attention of workers in India, the possibility of direct transmission taking place has never been lost sight of.

Our first discovery of the development of *Leishmania donovani* in the sandfly *Phlebotomus argentipes* was not a chance observation, but the result—fortunately the early result—of a campaign of investigation that had been decided upon some time before. From the data that we had collected we found that in the centre of Calcutta was a focus of intense infection, whereas in other parts of the city only imported cases were encountered. Now kala-azar is a disease that is usually associated with rural conditions, where artificial sanitation does not exist and arthropoda abound, and where to look for the special factor or factors associated with kala-azar transmission is looking for a needle in a haystack. This focus in Calcutta, however, where conditions were more standardized and flora and fauna less various, seemed to provide a great opportunity for investigating the conditions associated with kala-azar transmission, a second area in Calcutta, where there were many imported but no indigenous cases, serving as an excellent control. [The three important conditions noted were (a) vegetation in close proximity to the dwelling, (b) earth unprotected by cement or paving, in or around the dwelling, and (c) ground-floor residence.]

It would be wrong to say that this general survey gave us a direct pointer towards the sandfly, but it did narrow the field of investigation, it added strength to the suggestion that some species of sandfly might be the transmitter, a suggestion that had been made mainly on analogy with the supposed transmission of oriental sore by an insect of this genus, and as far as I was personally concerned it gave the first definite set-back to the theory of direct transmission that

hitherto I had favoured; the infected area was neither the most insanitary nor the most crowded area in the town, and in many more insanitary and more crowded quarters only imported cases could be found. At this point an entomological assistant was added to our enquiry and a survey of the arthropoda of this area was commenced. Our main attention was directed towards the phlebotomi and the culicoides. At first only sandflies of the 'minutus' group, primarily lizard feeders, were found, and then immediately the monsoon conditions set in *Phlebotomus argentipes* appeared in large numbers. (This early failure to find *argentipes* was in part due to inexperience as they are actually present in varying numbers throughout the year.) Laboratory breeding of these sandflies was immediately started and within a very few months we had demonstrated the development of leishmania into its flagellate stage in this species (Knowles, Napier and Smith, 1924). Christophers in Assam immediately switched over on to this line of inquiry and for some time everything seemed to be working to plan; he and Shortt (Christophers *et al.*, 1926, and Shortt *et al.*, 1926) demonstrated that the flagellate infection in this insect progressed anteriorly and that after a certain time the mouth parts were involved so that in taking a blood-meal the sandfly must inevitably infect the wound, and many other important observations were recorded that seemed to make it only a matter of months before the complete natural cycle of this infection would be worked out. It was just ten years ago, almost to the day, that the development of leishmania in this sandfly was discovered and yet to-day we cannot claim to have established the sandfly hypothesis beyond any possible dispute, in the way for example that the transmission of malaria by anophelines has been established; we have transmitted the infection from a kala-azar patient to a previously-uninfected hamster by the sole agency of the sandfly, *Phlebotomus argentipes*, on three separate occasions, but against these successful transmissions we have a large number of failures that are unexplainable in the present state of our knowledge, and we have so far entirely failed to transmit the disease to man by the agency of this sandfly; and yet we—I speak for myself and my colleagues at the Calcutta School of Tropical Medicine—are more convinced to-day than we were ten years ago that the sandfly is the main transmitter of kala-azar in India.

Putting aside the biological considerations—the development and anterior location of the flagellate infection in the sandfly by which it is distinguished from natural flagellate infections and which in the opinion of protozoologists is unlikely to be purposeless, and the fact that, in India, only in this species has such a degree of development been observed to take place—and the positive transmission experiments I have just referred to, let us enumerate and consider some of the points in favour of the sandfly hypothesis:—

(i) The sandfly, *P. argentipes*, has been found, in large numbers when looked for at the right time of year, in every kala-azar endemic area in India.

(ii) Though the geographical distribution of the sandfly does not correspond exactly with that of kala-azar, the species is found in large numbers for the greater part of the year only in those areas where kala-azar is prevalent.

(iii) Certain meteorological and physiographical conditions that have been found to be constant features of the kala-azar endemic areas, *e.g.*, alluvial soil, high rainfall, and an equable humid tropical climate, appear also to be essential for the breeding of this sandfly and for the full development of the flagellate infection within it, in nature and, as far as temperature and humidity are concerned, in the laboratory.

(iv) The kala-azar curve appears to correspond closely with the sandfly incidence curve, allowing for a 3 to 4 months' incubation period.

(v) The rural incidence of the disease, and the association with vegetation, unprotected soil and ground-floor residence when the disease occurs in a town. (These sandflies breed in soil in which there is a certain amount of nitrogenous matter, as supplied by household refuse or domestic animal droppings; they breed in the earth protected by the overhanging eaves of houses, under trees and bushes, or other heaps of refuse.)

(vi) The house incidence of the disease and the fact that moving an infected household to a new site will often break the infection chain. (Sandflies have a limited flight and therefore breed only near their food supply.)

(vii) In nature, this sandfly persistently feeds on man; about 33 per cent of the fed flies that are caught contain human blood; and whenever any considerable number of wild flies caught in an endemic area are examined some infected flies are always found.

(viii) During an epidemic or hyper-endemic period actual cases of kala-azar supply a rich source of infection for sandflies, an average of 15 to 20 per cent of the latter becoming infected after a single feed on a kala-azar patient.

(ix) During a hypo-endemic period there seems to be every reason to suppose that the majority of clinically-cured patients provide a continuous, though less rich, source of infection, *whether they show dermal lesions or not.*

Some explanation of this last statement is necessary. In India—at least in two of the main areas of endemic incidence of the disease—a common sequel to visceral leishmaniasis, *i.e.*, kala-azar, is dermal leishmaniasis. One particular manifestation of this condition was first described, only 12 years ago, as dermal leishmanoid, and was thought to be a rare complication of treated kala-azar, but this skin infection is now recognized to be a very common end-result of a visceral infection, whether treatment has been given or whether spontaneous cure has taken place, to display a large variety of clinical manifestations, and in some instances to display *no clinical manifestations whatsoever* (*vide infra*). The nodular, or 'dermal leishmanoid', type is by no means the most common, though probably it may be considered the most characteristic. The nodular, or any of the hypertrophic, forms are likely to bring the patient under medical notice; it is difficult to estimate the incidence of these but probably it would not be far wrong to say that in Bengal one per cent of treated patients developed lesions of this nature. The macular depigmented form is on the other hand quite likely to be overlooked by the patient; in a village treatment centre we made a rapid inspection of 120 patients who had been treated for kala-azar and cured clinically during the previous five years, and found well-developed macular lesions of dermal leishmaniasis in 6, or 5 per cent, of them.

Now these dermal lesions may appear on any part of the body, they sometimes appear all over the body, they are nearly always widespread; they appear more or less spontaneously on different parts of the body, and though the lesions do enlarge both centrifugally and centripetally there is no suggestion of direct extension of the infection along a limb or to other parts of the body, nor is there any evidence of lymphatic spread. Thus it seems apparent that the distribution of the infection is by the blood; and, as parasites are always present in the blood during the visceral phase but disappear from it when the patient is cured and are not found during the dermal phase, one must conclude that the dissemination of the parasites to their dermal foci takes place during the visceral phase. The lesions usually appear about one year after the signs and symptoms of the visceral attack have subsided; that is to say there is a latent period of about one year before the first clinical manifestations of the dermal infection appear, during

which time the parasites are lying more or less dormant in their dermal foci.

The dermal infection is apparently a fairly chronic condition, but it does sometimes clear up spontaneously, and this spontaneous recovery is more often noted in the case of the macular, depigmented lesions.

I put forward the suggestion some time ago (Napier, 1931) that, as about one per cent of kala-azar patients develop lesions that reach the hypertrophic stage and about 5 per cent develop lesions which stop at the macular stage, it is conceivable that a much larger percentage have a dermal infection that never reaches the clinical stage at all, or, to carry this hypothesis further, that a dermal infection is a constant sequel to a visceral infection, that in only a small percentage of these patients does the infection reach the clinical stage, and that though it may be difficult to demonstrate this skin infection histologically, sandflies will become infected after feeding on persons with this subclinical infection.

It has been shown that sandflies readily become infected when they feed on the nodular lesions of dermal leishmaniasis, on the macular depigmented lesions and even on areas of skin on which there are lesions so minute that they would be overlooked by the average medical man who had had no special experience of this condition (Napier, Smith, Gupta and Mukerji, 1933), and now Dr. Smith has carried this line of work one stage further; he has fed laboratory-bred sandflies on clinically-cured kala-azar patients in the convalescent stage, in whose blood-cultures no leishmania could be demonstrated, and has found that a quite considerable percentage of these flies became infected (I cannot give the exact figure as these investigations have not been completed, though I have Dr. Smith's permission to refer to them; however, I can say that it was not a matter of just one or two flies in a few hundred being infected). Finally, he has fed sandflies on one of the laboratory servants who had had kala-azar a year previously but who had no clinically-apparent dermal lesions at all, and he has found two or three infected out of a batch of about twenty (again, I am uncertain about the exact figures).

These few observations do not perhaps establish my theory *in toto*, but they do prove quite definitely that the ex-kala-azar patient who shows no clinical evidence of either visceral or dermal infection can act as a carrier of leishmania, and they lend strong support to the suggestion that a large number of these patients do remain as carriers for varying periods.

This seems to me to open up wonderful vistas of the epidemiology of the disease in the endemic areas; we have the three factors, (a) the ever-ready supply of the virus, (b) the sandfly transmitter and (c) the susceptible population. When conditions are sub-optimal, there are comparatively fewer sandflies and many of those that become infected do not live long enough to allow full development and transmission of the leishmania to occur, or, when there are too few remaining susceptibles in the population, then in either of these circumstances only sporadic cases will occur, or the disease may even appear to die out altogether in an area for a few years. In time a fresh susceptible population grows up and then, as (a) the supply of the virus is still present, it only requires a year favourable to sandflies for the occurrence of one of those exacerbations of kala-azar endemicity which characterize the history of the disease in India.

In rural areas the sandfly population is enormous (and sandfly control will I am afraid be a very difficult problem). I can give you some idea of the state of affairs when I tell you that Dr. Smith recently found as many as 200 larvae in a one-pound biscuit tin of earth collected in the neighbourhood of a kala-azar-infected hut in a village near Calcutta. However, in rural areas the population is scattered, it is a more

or less constant one, and the sandfly has many alternative hosts; on the other hand, in towns, conditions for sandfly breeding may be absent, and in these circumstances kala-azar is also absent, or the conditions may be such as to allow a limited amount of sandfly breeding, and then the density of the human population compensates for any deficiency in the sandfly population, alternative hosts are usually absent and the flies therefore concentrate on human hosts, and the population is less constant (that is to say it is frequently diluted by susceptibles), so that in these urban areas the incidence level is often high and the distinction between the periods of high and low incidence is always less marked than in the villages, where, as I have said, the disease will sometimes seem to disappear for a year or so.

I think it will be apparent to you that in this scheme it is not necessary to postulate that every infected sandfly 'bite' (I am speaking colloquially) will produce kala-azar; at the height of an epidemic wave (*sensu lato*) everybody in an infected village must be subjected to an enormous number of 'bites' by infected flies, and yet many, even of the most susceptible age groups, seem to escape infection. In this disease, as in most other diseases, the human resistance factor must play an important part, and whether it is a matter of repeated subjection to infected bites being necessary or whether some other factor determines the visceralization of the infection that the sandfly implants in the skin is not a matter that I propose to discuss here, though I consider that we have a strong case in favour of the second alternative; the point was raised to emphasize the fact that little importance need be attached to the apparent failure of our human transmission experiments.

This leaves our failure to imitate in the laboratory the conditions under which sandflies transmit kala-azar in nature, closely enough to ensure transmission of this infection to the susceptible hamster, not just now and then, because we have done this, but on every occasion that it is attempted, as the only point against our sandfly hypothesis of the transmission of kala-azar. On the other hand all our other laboratory observations, and every epidemiological observation that has been made in India, are in keeping with the hypothesis that the sandfly, *Phlebotomus argentipes*, is the normal transmitter of kala-azar in that country. The circumstantial evidence in favour of this hypothesis is so overwhelming, and the theoretical superstructures that we have built are so exactly in accord with epidemiological experience in the endemic areas that I hope you will see how difficult it would be for us to believe that they are founded on a fallacy.

Fig. 1.—The abdomen is opened and the edges of the wound are retracted showing the rupture on the anterior border and the diaphragmatic surface. On account of the operative position of the patient the enlarged spleen has moved more towards the middle line than is usual even for an enlarged spleen. Note how it overlies the stomach.

Fig. 2.—The spleen is rotated on its longitudinal axis with its anterior border lying outside the left edge of the operation wound. The rupture on the gastric surface is now well seen. Note the tense and swollen appearance of the pedicle with its peritoneal covering owing to accumulation of blood clots inside.

Fig. 3.—The capsule over the pedicle is opened, the clots evacuated and two clamps applied—one close to the spleen and the other immediately to the left of the commencement of the splenic ligaments.

Fig. 4.—The spleen is removed, the stump of the pedicle is peritonized and the divided adhesions are stitched up.

THE SURGERY OF THE RUPTURED SPLEEN

By P. BANERJEE, F.R.F.S., F.A.C.S., F.R.S.E.
LIEUTENANT-COLONEL, I.M.S.

Civil Surgeon and Superintendent, Medical School
Chittagong

The normal spleen

THE normal spleen is deeply placed in the abdominal cavity and protected from injury by its position. It is supported on all sides by important viscera among which it is wedged in. It derives its anchorage from folds of peritoneum usually spoken of as its ligaments.

The oblique longitudinal axis of this somewhat wedge-shaped gland corresponds to the 10th rib and its upper and lower limits, which correspond to the inner half of its anterior border and the outer third of its posterior border, lie behind and parallel to the upper border of the 9th and the lower border of the 11th ribs, respectively.

Its apex lies about $1\frac{1}{2}$ inches from the spinous process of the 10th dorsal vertebra and its base, a small concave and triangular area, rests on the splenic flexure of the colon and the phrenico-colic ligament at the 11th rib about $3\frac{1}{2}$ inches away from the middle line looking downwards, inwards and slightly forwards.

The anterior border sharp, notched and somewhat convex separates its superior or diaphragmatic surface from the gastric half of its inferior or visceral surface.

The posterior border rather straight, thick and rounded lies between the superior surface and the renal half of the visceral surface.

The superior surface smooth and convex rests on the diaphragm, which separates it from those portions of the left lung and pleura occupying the interval between the diaphragm and the 9th, 10th and 11th ribs with the intervening intercostal spaces. This surface looks obliquely upwards, backwards and to the left.

The inferior surface is divided into two unequal halves by a longitudinal ridge extending from the apex to the upper angle of the triangular base. It is the shape of this surface that gives the organ its wedge-like appearance. The upper and larger half of this concave surface, which looks upwards, forwards and inwards, supports a portion of the stomach while the lower and smaller half, also concave but looking downwards and medially, rests on the upper half of the anterior surface of the left kidney and occasionally on the left suprarenal gland also.

The hilus of the spleen, a longitudinal and irregular cleft on its gastric surface about $2\frac{1}{2}$ inches long through which the 5 or 6 main branches of the splenic artery pass into the substance of the gland and a similar number of tributaries of the splenic vein pass out, lies about $\frac{1}{4}$ inch above and parallel to the ridge dividing the gastric from the renal area of the inferior surface.

The pedicle of the spleen composed of its vessels rests partly on the tail of the pancreas.

The surgical anatomy of the spleen, normal and enlarged

The peritoneal investment of the spleen.—The spleen is completely invested by the peritoneum except for an oval area round the hilus where its blood vessels enter its substance. Here the peritoneum leaves the capsule and lies loosely over the vessels and the pancreatic tail.

The spleen therefore may be said to lie as it were in a peritoneal pouch of which the serous covering of the pedicle forms the neck.

From the gastric and renal surfaces of the spleen the peritoneum passes on to the postero-inferior surface of the stomach and the anterior surface of the kidney, respectively. The angular space left between these two diverging folds covering the stomach and the kidney is lined by a portion of the peritoneal diverticulum, which forms the omental bursa.

In this way is the spleen attached to the stomach and the kidney by two separate double folds of peritoneum, known respectively as the gastro-splenic and the lienorenal ligaments.

As mentioned before, the triangular base of the spleen rests on the peritoneal shelf, the phrenico-colic ligament, a fold of peritoneum reflected from the splenic flexure of the colon to the left lateral abdominal wall at the 11th rib.

The splenic peritoneal ligaments do not interfere with its rhythmical expansion and contraction nor hamper the temporary increase in its size during digestion, nor its permanent enlargement due to disease.

Under normal conditions, it is possible to pass one's hand round the spleen, i.e., between it and the viscera that surround it.

The cone-shaped peritoneal space, having its base at the hilus and the bare area of the spleen immediately surrounding the hilus and its apex at the point where the splenic peritoneum is reflected over the stomach and the kidney, is occupied by the tail of the pancreas, the lienal vessels and their main branches, as described above, and is capable of considerable distension without tearing as seen in rupture of the spleen when it is often filled and distended with clotted blood.

If a coloured fluid is introduced under pressure through a small opening in the peritoneum over the splenic pedicle, the fluid will be seen to pass through the folds of peritoneum forming its ligaments in the direction of (1) the postero-inferior surface of the stomach where it is soon stopped, and (2) the lateral half of the anterior surface of the left kidney. In the latter situation the peritoneum from over the kidney is more easily lifted up and the fluid may descend along the lateral border of the kidney to the retroperitoneal space behind the descending colon.

In the case of a diseased and enlarged spleen the peritoneum over the kidney is on the stretch and is still more easily raised and enables the fluid to pass into the post-colic retroperitoneal space.

In severe injuries to the spleen the hæmorrhage is partly intracapsular and partly extracapsular. The intracapsular hæmorrhage passes in a similar way through the peritoneal sheath covering the pedicle and between the leaves of the splenic ligaments to the retroperitoneal area behind the descending colon.

Except at the hilus where the spleen capsule, which is described later, is invaginated into it along the blood vessels entering it, the peritoneum is inseparably adherent to the capsule. The spleen is kept in place not only by its peritoneal anchorage but also by the stomach and the kidney pressing it against the diaphragm. Thus a moderate enlargement and increase in weight are not sufficient to dislodge it from its position.

When, however, a spleen is considerably enlarged and heavy there is a risk that its weight and the physical exertions of the individual will dislodge it from its position. When this happens it is rotated through a semi-circle on its antero-posterior axis and is suspended by its pedicle with the diaphragmatic surface looking downwards, the anterior border obliquely directed forwards from left to right, and the base directed downwards and to the right. The pedicle may be still more stretched and lengthened, on account of the increasing weight of the spleen; the organ may descend into the pelvis or even wander about in the abdominal cavity in response to the changes of position of the patient.

The rarity of such an occurrence in Bengal, where spleens greatly increased in size are so very common, is due to the gradual enlargement of the gland and to its contracting firm adhesions with the diaphragm as a result of perisplinitis at an early stage.

Ordinarily, however, the diaphragmatic surface and the anterior border, on account of the enlargement, come to the surface by displacing the colon and the

coils of the small intestine and occupy the whole of the left hypochondriac space from its anterior to its posterior wall. The base descends into the left lumbar region and the notched anterior border also follows the base in its descent; here they may be easily palpated and the movements upwards and downwards of the spleen in obedience to the respiratory excursions of the diaphragm appreciated.

The mechanisms of rotation and of rupture of an enlarged spleen

The mechanism of the descent of the enlarged spleen, which occupies the whole of the left hypochondriac region from its anterior to its posterior wall, involves a rotation on its antero-posterior axis to descend into the lumbar region past the constriction at the waist below the 12th rib.

This rotation changes the direction of the longitudinal axis of the spleen from an oblique to a more or less perpendicular position, and thus places its anterior border at right angles to the anterior costal border.

The enlargement of the spleen extends uniformly in all directions and as a result its anterior border often curves over even the anterior surface of the stomach sometimes almost completely separating it from the anterior abdominal wall on the left.

Rupture of the spleen is caused by the anterior costal border being driven into its anterior border. Hence the tear always lies across the spleen and passes between the bundles of the circularly disposed muscle fibres of its capsule. It may extend both ways into the gastric and diaphragmatic surfaces, but usually it extends more on the latter than the former, because of the superficial position of the diaphragmatic surface and its direct contact with the lower ribs anteriorly.

Owing to the enlargement, descent, and rotation of the spleen, its pedicle is not only lengthened and its direction changed from the transverse to one downwards and outwards, but it also loses contact with the tail of the pancreas, which does not accompany it in its descent.

Occasionally, however, when the spleen is not greatly enlarged the pedicle may still maintain its contact with the pancreatic tail and even contract firm adhesions with it difficult to separate.

The splenic vessels

The splenic artery is a branch of the celiac artery. It passes to the left along the upper border of the pancreas in a remarkably tortuous manner behind the stomach and the omental bursa and reaches the hilus of the spleen between the folds of the lienorenal ligament. Here it divides into 5 to 6 branches, which enter the spleen substance through the hilus.

The subdivisions of these branches, which are end arteries and are distributed along the transverse axis of the spleen, escape injury in any rupture of the spleen that passes across its anterior border and therefore parallel to them.

The splenic vein has a similar horizontal course from left to right across the abdomen. It is straight and not tortuous, and lies below the artery and behind the posterior surface of the pancreas, where it is subject to considerable pressure when the stomach is full and presses back the pancreas posteriorly.

It joins the superior mesenteric vein at right angles to the latter behind the neck of the pancreas and is therefore placed at a great disadvantage in draining into it specially during periods of active digestion when the superior mesenteric vein is engorged with blood.

At the hilus of the spleen, where it is formed by 5 or 6 tributaries, and in the pedicle, the splenic vein with the splenic artery lies on the tail of the pancreas, which is posterior to them in this situation.

The main tributaries of the splenic vein in the spleen pulp are disposed like the arteries on the transverse axis of the gland.

The short gastric and the left epiploic branches of the splenic artery are given off at the apex of the V-shaped junction of the gastro-splenic and lienorenal ligaments; they pass between the folds of the former to be distributed to the stomach and do not in any way interfere with an operation for splenectomy.

Structure of the spleen

Besides its serous covering the spleen may be said to consist principally of a fibro-muscular capsule, a supporting framework of reticulated tissue inside the capsule and the spleen pulp made up of blood and various types of cells, which fill in the interstices of the reticulum.

The capsule is strong, and is composed mainly of elastic tissue and unstriated muscle fibres, which are circularly arranged round the longitudinal axis of the spleen and on account of their elasticity are normally capable of considerable expansion without rupture. The capsule is invaginated through the hilus over the blood vessels entering the hilus. Processes of this capsular tissue passing from the inner surface of the capsule and the surface of the blood vessels divide the spleen into small trabeculae. These trabeculae are further subdivided into a fine, microscopic reticulum by the reticular cells with processes radiating from their cytoplasm.

The branches of the splenic artery on entering the spleen divide and subdivide. The subdivisions lie in the direction of the transverse axis of the spleen and do not anastomose with each other, but gradually getting thinner and smaller in size end in cones of minute twigs, which lose their arterial walls and

Diagram of a dissected specimen of splenic artery in the Anatomical Museum of the Vienna University showing the transverse and parallel directions of the main branches of the artery, which do not anastomose and which terminate as minute end-arteries.

retain only the endothelial coats. The endothelial coats soon get fenestrated and bulbous and are finally merged in the reticulum of the spleen pulp.

The splenic vein commences in the same way as the artery ends, that is, as pencils of minute tributaries, which have a fenestrated appearance as they are formed from endothelial cells, which seem to be derived from modified connective tissue corpuscles. These fenestrated endothelial tubes soon acquire a covering and are formed into small veins, which by coalescence form larger and larger ones and finally leave the spleen at the hilus as the 5 or 6 main tributaries, which anastomose to form the splenic vein immediately on their exit from the spleen.

Although the main tributaries of the vein inside the spleen lie along its transverse axis like the arterial branches, they, unlike the latter, anastomose with each other to a great extent.

The coats of the arteries are surrounded by lymphoid tissue, which at places is concentrated into definite nodules.

The nodules are known as the Malpighian corpuscles and are visible as small whitish specks to the naked eye.

In the meshes of the reticulum the arteries empty their contents.

Functions of the spleen

The normal functions of the spleen are stated to be (1) storage of iron, (2) beginning the formation of bilirubin from hæmoglobin, (3) filtration of bacteria and protozoal parasites, (4) manufacture of antibodies and lymphocytes, and (5) reduction or destruction of erythroblasts.

But it is with the structural peculiarities of the spleen, its rhythmical expansion and contraction, and the mode of circulation of blood in it that we are mainly concerned.

Circulation in the spleen

Blood entering the spleen through its arteries first passes into the splenic reticulum through the inter-endothelial open spaces in the bulbous ends of the terminal branches of the arteries and is finally poured into the boggy mass of the spleen pulp by the abrupt opening of these branches in its midst.

Thus there is a sudden considerable fall of blood pressure and slowing of the circulation in the spleen, a condition for which there is no parallel in any other organ or tissue of the human body.

The increased density and viscosity of the blood, due to its admixture with numerous cells of various types present in the spleen pulp with its reticular framework, cause a further retardation of circulation through the spleen.

This abnormal stagnation of blood would be impossible to overcome by the ordinary mechanism of circulation if it were not for the elastic and contractile character of the spleen capsule, its trabeculae, and the splenic rhythm, which help to overcome the inertia and maintain a constant, but greatly retarded, venous flow through the spleen.

Circulation during digestion

During periods of active digestion the spleen is enlarged in size on account of an increase in the flow of arterial blood and a further decrease in the rate of venous blood flow. In the earlier stages of digestive activity a greatly increased volume of arterial blood is distributed in the digestive tracts and glands. In this distribution the spleen has its share. But while the arterial flow is increased the rate of venous flow in the spleen is not only not increased but, as the process of digestion proceeds, is further retarded by congestion in the portal system on account of the superior mesenteric vein bringing back to the portal vein a much larger volume of venous blood than usual.

The splenic vein joining as it does the superior mesenteric at right angles to the latter and lying behind the pancreas and the stomach is placed at a great disadvantage in emptying its contents owing not only to the congestion referred to above but also on account of (1) the direction of its venous blood current at right angles to that of the portal vein, and (2) the pressure exerted on it by the now active pancreas and the full stomach.

The splenic rhythm now fails to overcome the obstruction sufficiently to maintain the ordinary rate of venous outflow from the spleen and enable it to retain its normal size. We have therefore an increase in its size and a temporary venous congestion physiological in character with a rise of blood pressure inside it above its normal.

Its sluggish circulation, the greater density and viscosity of the blood in its pulp and the presence in this blood of the products of the cells destroyed or disintegrated in it render the loss of blood a very slow process in rupture of the spleen.

To the same factors may also be attributed a quicker coagulation than normal of the effused blood within the spleen capsule, round the spleen, and in the retroperitoneal space with which its capsule communicates.

Pathology of the rupture of an enlarged spleen

By an enlarged spleen is here meant a spleen which is suffering from a chronic enlargement due to a chronic inflammatory process, the result of such pathological conditions as malaria and kala-azar.

The enlarged spleen while retaining its shape may attain many times its normal size; there is a proportionate increase in weight. A spleen removed by me 5 to 6 hours subsequent to its rupture weighed seven pounds after removal.

Its relations to other viscera remain unchanged, though it may push the costal arch forward and outward on the left side, and present its base and anterior border several inches below the arch.

While the size of the splenic artery and its branches, which enter the hilus, are but moderately increased there is a compensatory dilatation of the vein proportionate to the increase in size of the spleen and it may attain as much as four times or more its normal size.

The splenic dullness, which normally can be outlined by percussion posteriorly, is now well marked over a large area anteriorly also.

These changes in size and weight of the spleen, distressing as they are to the patient on account of the pressure exerted by them chiefly on the stomach, lungs, and the heart, would add to the difficulties of its removal, were it not for the adhesions with the diaphragm and the neighbouring viscera as a result of perisplenitis. Thus it may be found adherent to the stomach, the colon, and to the diaphragm; the kidney, however, always escapes.

The extent of such adhesions varies considerably and so does the difficulty of removal of the spleen. The capsule and the trabeculae are also hypertrophied in response to the enlargement.

It is difficult to imagine therefore that an enlarged spleen may rupture spontaneously. I never found a case of rupture where careful inquiry failed to elicit a definite history of injury.

The frequency of rupture of an enlarged spleen, I believe, is due chiefly to its accessibility as compared to the normal spleen. The enlarged spleen, lying next to the parietes and immediately behind the lower ribs with its anterior border and base frequently descending beyond the left anterior costal border at right angles to it, is exposed to trauma.

This view is supported by the fact that the seat of rupture is always at its anterior border, which is most accessible to trauma. The further fact that most often the injury to the spleen pulp is deep and extensive and out of all proportion to the tear in the capsule proves that the hypertrophied capsule even under such abnormal conditions is resistant to violence.

Next to accessibility, its semi-solid consistence held in by its capsule renders it more liable to rupture than the hollow viscera in its neighbourhood.

Thus it is rather the exception than the rule to find any serious injury to any other neighbouring viscus to be associated with the rupture of an enlarged spleen.

A study of the nature of the injury which caused rupture in 19 cases of enlarged spleen that came under my care showed direct violence in some form or other to have been responsible for them all.

The nature of the injury in the order of frequency was as follows:—

1. Knocked down by a motor car.
2. Knocked down by a bullock cart.

3. Kicked by a man.
4. Kicked by a horse.
5. Blow with the fist over the spleen.
6. Fall from a tree in the prone position.
7. Fall of a load on the abdomen.
8. Fall of a heavy load on the back which doubled up the patient driving the lower ribs into the spleen.

The history of each patient and the nature of the violence sustained by him, which in every case acted directly over the enlarged spleen lying partly in the left hypochondriac and partly in the left lumbar regions, showed that the rupture was caused by the anterior halves of the lower ribs or the left anterior costal border having been driven into the anterior border of the spleen.

The lower ribs (8th, 9th and 10th), owing to their articulation posteriorly with the bodies and transverse processes of the vertebrae to which they are connected by powerful ligaments and their attachment anteriorly by single facets and thin ligamentous bands to each other's cartilaginous ends, have only a slight, rotatory movement at the neck in their longitudinal axes, but enjoy considerable freedom of movement and elasticity anteriorly.

Thus when they are driven backwards by force against the anterior border of the spleen across which they lie one or more tears in the capsule are produced, some trabecular bands are torn and the spleen pulp is more or less crushed or contused.

The rupture of the capsule may extend on either side of the anterior border to the gastric and the diaphragmatic surfaces. Rarely is there more than one line of rupture and, although the depth to which it apparently encroaches into the spleen substance varies, the intracapsular laceration of the pulp all round the tear is usually considerable. This laceration or contusion of the pulp is caused by the impact on the spleen of the blunt agent of the violence, which drives in the rib or ribs before it.

I have seen only one example of intracapsular laceration of the pulp without an external tear in the capsule. There was only an indentation on the anterior border but considerable retroperitoneal hæmorrhage.

The abdomen was opened because of the symptoms of rupture. No intraperitoneal hæmorrhage was found but an examination of the spleen showed intracapsular clots over the gastric surface in the region of the hilus. While the spleen was being removed extensive extravasation of blood in the retroperitoneal space behind the descending colon was discovered and evacuated.

The stomach, the colon, and the ileum, which are in close anatomical relationship to the spleen, are very rarely injured. The explanation of this immunity lies in the facts that they are all hollow, elastic and compressible viscera, which lie protected under cover of the enlarged spleen, which displaces them from the surface, itself encroaching on the surface areas previously occupied by them.

Equally immune is the spleen pedicle. Except in very severe and rare crushing injuries of the thorax and the abdomen when other vital organs besides the spleen, such as the liver and the lungs, are also seriously injured leading to almost instantaneous death, the pedicle always escapes injury owing no doubt to its deep situation and the protection afforded it by the enlarged concave gastric surface and the overhanging anterior border.

Hæmorrhage in rupture of an enlarged spleen

Hæmorrhage after rupture of an enlarged spleen is very slow for the following reasons:—

1. The low pressure of blood in the spleen pulp.
2. Reflex and spasmodic contraction of the capsule after the injury narrowing the openings of the trabecular meshes.

3. Early intracapsular coagulation of the extravasated blood.
4. The escape from injury of the main branches of the artery and the vein, which enter the spleen at the hilus, and lie transversely across the spleen pulp and therefore parallel to the direction of the rupture and not across it.
5. The injury to the blood vessels is confined mainly to the capillaries.
6. Suspension of the splenic rhythm.

The course taken by intracapsular hæmorrhage and the mechanism of this extravasation has already been described.

Intraperitoneal hæmorrhage first collects round the spleen in the left hypochondriac and lumbar regions and thence trickles down into the pelvic cavity and may overflow into the right paracolic gutter if not early arrested by operation.

The extravasated blood soon coagulates in lumps of various sizes, which are freely intermixed with fluid blood.

Symptoms

The symptoms of a ruptured spleen which are first to appear are shock, pain, tenderness and well-marked hyperæsthesia over the left hypochondriac region.

The clinical signs of the catastrophe are slow and gradual in their onset. Thus the cardinal symptoms of hæmorrhage, such as shifting dullness in the abdomen, pallor, changes in the rate and tension of the pulse, fall of blood pressure, shallow and rapid breathing, develop to an appreciable degree such a long time after the onset of hæmorrhage that if the surgeon waits for them for the confirmation of his preliminary diagnosis the auspicious moment for effective surgical interference will have passed.

The hesitation in coming to a decision is chiefly due to a not-unnatural expectation to find the more serious and later symptoms in the early stage of the injury. Such expectation in the inexperienced is bound to be disappointed.

Had I not followed the golden rule in emergency abdominal surgery of opening the abdomen when in doubt, even in the very first case of rupture of the spleen that I came across, several lives would have been lost, others jeopardized, and experience gained at a high cost.

Shock, although constant, varies in degree but is very seldom acute and alarming, as is usually stated in textbooks. Patients have sometimes walked into the hospital with slight assistance from friends within a short time after the injury complaining only of pain and tenderness over the left hypochondrium.

Pain, tenderness and hyperæsthesia, however, are well marked and should be the deciding factors for immediate surgical interference. Associated with them there is most often to be found an enlarged and palpable spleen. Great care and gentleness should be exercised in palpation to discover it and the patient should not be urged to increased respiratory efforts, if there is any difficulty in appreciating it on account of the presence of the reflex muscular rigidity over the left hypochondrium.

This parietal motor reflex, the spasm of the fibromuscular capsule of the spleen and the diminished respiratory excursions are helpful in retarding or even in arresting the venous oozing.

A patient brought to hospital 3 to 4 hours after the injury, by a doctor who had made a quick diagnosis and rendered first aid by bandaging the lower part of the thorax and the whole of the abdomen with a *dhoti*, showed only slight hæmorrhage on opening the abdomen although the rupture was about 2½ inches in length and about ¼ inch deep.

Where the spleen is not greatly enlarged and descends but slightly below the costal margin it may not be palpable 2 or 3 hours after the injury on

account of its decrease in size following loss of blood and the spasmodic contraction of its capsule.

Pallor by itself is an inconclusive sign as most of the patients subject to pathological spleen suffer from a varying degree of anaemia; but when it is associated with the other cardinal symptoms of hæmorrhage it is of some significance in diagnosis.

The initial fall of blood pressure due to shock is not considerable and is recovered from soon after the trauma.

Definite and appreciable softness and quickness of the pulse, except in rare instances, can only be felt from 6 to 7 hours after the injury. Thus patients brought in early to hospital often have an almost normal pulse, temperature and blood pressure.

Air hunger and restlessness are the last signs to appear and indicate the final stages of the tragedy.

Shifting dullness is not early appreciable and, although it can be perceived at a later stage of the hæmorrhage, the movements necessary to elicit it may prove injurious to the patient. The time of its onset varies in individual cases in accordance with the amount of bleeding.

An aseptic general peritonitis manifested by well-marked but not excessive rigidity of the whole of the abdominal wall and obstinate constipation may develop 24 hours after the injury if the patient is still alive. Even at this stage pain is chiefly localized at the left hypochondrium and is only slightly diffuse.

This symptom was well seen in a boy of eight, who sustained a rupture of the spleen as the result of a fall from a tree in the prone position. The hæmorrhage was slow and the symptoms though definite were not alarming at any stage and the boy's mother, a widow, at first refused permission to an operation on her only child. General abdominal rigidity without much pain was definitely perceived after 24 hours. The rigidity and the obstinate constipation persisted until the abdomen was opened 72 hours after the injury and the effused blood, which was distributed all over the peritoneal cavity with a lot of clots in the pelvis, was quickly aspirated and sponged out and the spleen removed.

The child's bowels moved with a small soap-water enema 8 hours after the operation and thereafter naturally and normally. The recovery was uneventful.

There was a small shallow tear about half an inch long and about an eighth of an inch deep over the anterior border of the spleen. Any clot, which might have sealed the rupture, was not visible when the spleen was examined after clearing out the peritoneal cavity. It was about twice its normal size.

A consideration of the symptoms as described above leaves no doubt as to the need for immediate surgical interference.

Acute pain, tenderness and hyperæsthesia over the left hypochondrium immediately following an injury of that region in a patient suffering from enlarged spleen or in a patient with a history of malaria or kala-azar form sufficient justification for an exploratory laparotomy. We should not await the advent of the late symptoms, if we wish to save the patient's life.

In 18 out of 19 cases that came under my care the diagnosis was made on the early symptoms and spleenectomy performed immediately. The patients all came to hospital within 4 to 6 hours after the injury, survived the operation, and had uneventful recoveries.

In the one case in which death followed the operation, the patient was a boy of 12 whom I saw 18 hours after the injury and after practically all the fatal symptoms had developed. Even his life possibly could have been saved if an immediate blood transfusion had been possible.

Treatment

In every abdominal catastrophe first aid and immediate and careful removal of the patient to hospital are of prime importance, and, if carried out by the

attending physician, profoundly modify the prognosis of the case.

In suspected rupture of the spleen, the abdomen should be carefully bandaged over a pad with the knee and hip joints in a flexed position. The bandage should be efficiently and tightly put on. Commencing from the xiphoid process and lower part of the chest, it should extend down to the symphysis pubis. This not only limits respiratory excursions and diminishes pain due to movement to a minimum, but also helps to arrest the hæmorrhage by increased pressure on the spleen, which is already contracted as a result of the trauma. The effused blood is held in round the spleen in the left hypochondrium and coagulation is accelerated.

The patient should be placed on his back with the body in a slanting position, the head being on a lower level than the feet, i.e., in a moderate degree of Trendelenburg position.

The question of administration of morphia is a difficult one to decide. If the attending doctor is a surgeon or experienced in surgical diagnosis and is sure of his finding, he will be justified in giving a hypodermic injection of a $\frac{1}{2}$ grain of morphia, especially if the patient has to be carried over a long distance to hospital and some time must necessarily elapse before he can reach it.

If, however, the patient can be quickly taken to hospital, it is best not to give any morphia as it masks the symptoms of pain, tenderness, cutaneous hyperæsthesia and the motor reflex.

When possible, slow subcutaneous infiltration of normal saline in the chest or the axilla should be given at once. This does not raise the blood pressure even if pushed to the extent of 2 pints, but on the contrary helps in the recovery from shock and counteracts the effects of loss of blood from hæmorrhage. This is seldom done, but on the rare occasions when it was, I found the patient a much better operative risk, because of the practically normal condition in which he was brought to hospital, in spite of the severe injury to his spleen.

If this has not been done, as is usually the case, no time should be lost in administering saline immediately the patient arrives in hospital.

Morphia should be administered as soon as the diagnosis is made. I have always given $\frac{1}{2}$ grain of morphia hypodermically without atropin in all my cases without any ill-effects. The patient, unless he is an opium-eater, goes to sleep in a few minutes.

Anæsthesia

I have found one per cent novocaine infiltration anæsthesia in successive layers of tissues as the operation proceeds, with the preliminary dose of morphia administered hypodermically 15 to 30 minutes before the operation, quite sufficient.

In nervous patients, who insisted on a general anæsthetic, a few whiffs of ether in addition were all that I found necessary.

Novocaine infiltration should extend for 3 inches laterally on each side of the line of incision along its whole length. I have often injected 250 to 300 c.cm. of the fluid with highly satisfactory relaxation and no subsequent harmful reaction of any kind.

However, spinal anæsthesia administered at a suitable level by an experienced anæsthetist I consider to be the best.

Position of the patient on the operation table

The best access is obtained by placing the patient in a reversed Trendelenburg position at an angle of 45 degrees with the table and with a similar inclination to the right.

This position drags the heavy, enlarged spleen downwards and towards the middle line and removes the intestines away from the site of the operation. Sand-bags should be so placed under the left loin as to arch the hypochondrium forwards.

The operation

The only incision used by me is a straight left paramedian incision about half an inch from the middle line, extending from as high a point on the left side of the subcostal angle as possible to 3 inches below the umbilicus.

With the position of the patient as described and complete relaxation of the parietal muscles on either side of the incision due to novocaine infiltration, very good access is obtained with suitable retractors.

As one dissects down to the peritoneal cavity nothing abnormal is generally noticeable, except occasionally the rupture of a few muscle fibres, until the peritoneum is reached when its tell-tale purple discoloration is at once seen.

On opening the abdomen there is a rush of blood whose venous character is at once apparent. Usually the pelvic cavity is found full of clots mixed with a little fluid blood. In the left paracolic gutter the situation is somewhat similar, but the spleen is generally drowned in fluid blood and only a few clots are seen near it.

The retroperitoneal spaces communicating with the hilus as well as the hilus itself are most often packed with coagulated venous blood.

Unless there is a considerable effusion of blood within a short time due to an extensive rupture deep in character or unless the patient has been made to move from side to side to elicit shifting dullness, as is unfortunately often done, the right side of the abdomen is found free from blood if it is opened within 3 to 4 hours after an injury.

In none of these cases did I find any injury to any other viscera associated with the rupture of the spleen.

All blood and clots are quickly removed by aspiration and with the help of large, warm sponges by an assistant.

In the meantime the surgeon should feel for the hilus, which is easily found, and press on the pedicle with the left hand, while with the right hand he searches for the rupture on the anterior border, as it generally extends both ways, i.e., towards the gastric and diaphragmatic surfaces from this border. The tear can easily be distinguished from the notches by its rough surface and its extent, although it lies parallel to them.

As soon as visibility is secured by the removal of blood and clots the pedicle should be handed over to the assistant to control while the surgeon continues his examination of the spleen and its surroundings.

Adhesions, of varying degrees, to the stomach, diaphragm and colon are always found, and prevent not only the rotation and evisceration of the spleen, but also render the use of clamps on the pedicle difficult or even impossible.

While the assistant stands to the left of the surgeon, both being on the right side of the patient, exercising what pressure he can on the pedicle, the surgeon divides the adhesions between clamps. When they are all cut through and the spleen is at last free, the assistant goes to the left of the patient and firmly grasps the spleen with a towel. The spleen is now rotated backwards by the assistant on its long axis to curve its pedicle forwards and two large curved clamps are easily applied on the generally abnormally long pedicle with the right hand of the operator, while with the left hand he firmly grasps it at its farthest right-hand extremity.

One clamp is applied flush with the hilus and the other an inch or so away from it to the right. As I have already said an enlarged spleen with its more or less elongated pedicle easily permits this.

I have never brought the spleen out of the abdomen. It is often too large and heavy to be safely manipulated out without the risk of serious damage to the pedicle.

Generally the pedicle is so broad and thick, owing to the enlargement of the veins and the stretching of

the peritoneum over it by adhesions and due also to a collection of clots inside the peritoneal sheath of the pedicle, that it is expedient to use two pairs of forceps instead of one at each of the two points indicated, one being applied from above and the other from below.

A preliminary incision of the sheath over the hilus and the pedicle anteriorly, to expel the clots and separate the pancreatic tail from the pedicle when necessary and possible, can be easily effected and is helpful in the efficient application of the clamps.

The tail of the pancreas lies behind the lower border of the pedicle and is easy of access. If it is firmly adherent to the pedicle, its sheath and the spleen, the right-side clamp or pair of clamps should include in its grasp both the pedicle and the tail of the pancreas.

The spleen is removed by cutting through the pedicle to the left of the pair of forceps nearest to the hilus, but the incision has sometimes to be made through the spleen substance.

The pedicle is tied with two stout chromic gut ligatures, transfixed and applied one between the clamps and the other in the immediate proximity to and to the right of the clamp placed nearest to the middle line of the body, and the clamps are taken away. The cut end of the pedicle is covered by peritoneum, as well as the circumstances allow.

The divided perisplenic adhesions on the stomach, the diaphragm and the colon are now tied with catgut, or, if long, as they often are, their cut edges are brought together quickly by continuous sutures, and the clamps removed.

When of necessity the tail of the pancreas has to be clamped and later on tied, no ill-effects are produced. I think the only danger of tearing it or cutting into it, is in trying to separate the intimate adhesions by blunt dissections or by excising them with a knife or a pair of scissors. The adhesions of the tail are generally very close and firm.

I never wasted time in attempting to tie the blood vessels separately.

It was my usual practice to leave a pint of sterile normal saline solution in the pelvic cavity before closing the abdomen, which was done in the usual manner in layers without drainage.

Some particulars of the cases operated upon

There were 19 cases in the series with one death. The ages of the patients were from 8 to 42; they were all males.

The average time taken to perform the operation was 25 minutes.

Every one of the patients gave a history of suffering for a long time either from malaria or kala-azar.

In 11 out of the 19 cases there were retroperitoneal hemorrhages.

In 16 cases the operation was performed 4 to 8 hours, in two cases more than 18 hours (of these one died), and in one case about 72 hours after the injury. In this last instance the patient survived the operation and made a good recovery.

Blood transfusion was carried out in only two cases, both of whom survived the operation. I consider blood transfusion unnecessary if the patient is operated on early.

The convalescence in those cases that survived the operation was rapid and uneventful. The removal of the diseased spleen seemed to bring about a rapid recovery.

The cases were not followed up, but two of the patients, who came to see me over a year after the operation were in perfect health and stated that they were enjoying much better health after the operation than before it.

Unfortunately systematic examinations of the blood prior and subsequent to the operations were not carried out and hence no statement as to blood changes can be made.

The following is a summary of the special features in the anatomy, pathology, symptoms and treatment of the rupture of an enlarged spleen.

1. An enlarged spleen is most exposed to trauma on account of its superficial position lying as it does next to the parietes in the left hypochondriac and lumbar regions. In fact it forms the most prominent abdominal landmark of a person suffering from chronic malaria or kala-azar.

2. It fills in these spaces from the anterior to the posterior wall and in its descent rotates round its antero-posterior axis to get past the constriction of the waist at and below the 12th rib, and lies in its new position with its anterior border across the left anterior costal border.

3. The constancy of the situation of the rupture across the anterior border is due to its being the anterior-most part of the spleen lying across the lower ribs, which are driven into it by direct violence.

4. The contusion or laceration of the pulp is generally extensive and out of all proportion to the

superficial extent of the rupture and is caused by the impact of the blunt instrument of the force, which follows the ribs.

5. The extreme rarity of any injury to any other viscera being associated with the rupture of an enlarged spleen.

6. The usual slow progress of the hæmorrhage.

7. The frequency of retroperitoneal hæmorrhage and the channel through which it takes place.

8. The slight degree of initial shock.

9. The development of the serious symptoms 6 to 12 hours after the injury is sustained.

10. The importance and benefit of first aid, which greatly improves the prognosis.

11. The importance of diagnosis on the initial symptoms.

12. The need of immediate operation, and its success in saving the patient's life, if performed early.

13. The need of quickness in the operative procedure.

Medical News

FIFTEENTH INTERNATIONAL PHYSIOLOGICAL CONGRESS, LENINGRAD-MOSCOW, 9TH TO 17TH AUGUST, 1935

According to the decision of the Fourteenth International Physiological Congress in Rome, the Fifteenth International Congress will be held in the U. S. S. R.

The Congress will take place in Leningrad and Moscow, 9th to 17th August, 1935.

The Committee will provide board, lodging, etc., for all the members of the Congress and dependent members of their families. Arrangements will be made for trips and visits to several parts of the country at reduced rates. In order to avoid any delay with visas, and to procure the best conditions of life and work for the members of the Congress, all the physiologists intending to take part in the Congress are requested to enlist as soon as possible.

The membership fee, Rbls. 10 = 131 Francs 34 Centimes Gold, should be forwarded to the following address: The State Bank of the U. S. S. R., Moscow, Current Account No. 7005 of the Committee of the Fifteenth International Physiological Congress. The cheque can be drawn in any currency according to the exchange rate of the day. Name and address of the sender should be given to the bank.

Detailed information as to the programme of the Congress, life conditions, trips, etc., will be issued in the near future.

Please address mail concerning the Congress: Leningrad, Main P. O., Box 13.

THE COMMITTEE OF THE CONGRESS.

THE FACULTY OF TROPICAL MEDICINE AND HYGIENE, BENGAL

The following students are declared to have passed the D.T.M. Examination, session 1934-35.

Passed

1. Amar Jit Singh, M.B., B.S. (Punjab), Assistant Bacteriologist, Clinical Laboratory, Patiala State—Awarded the 'Chuni Lal Bose' Gold Medal, 1935.
2. Jyotirmoy Banerjee, M.B. (Cal.), D.P.H. (Cal.), Private Practitioner.
3. Hans Raj Bhambi (Rai Sahib), L.M.P. (U. P.), L.T.M. (Bengal), Sub-Assistant Surgeon, Government of Punjab.

4. Provash Chandra Bhattacharyya, M.B. (Cal.), D.P.H. (Cal.), Private Practitioner.
5. Pundarikaksha Prasad Bhattacharyya, M.Sc. (Cal.), M.B. (Cal.), D.P.H. (Cal.), Private Practitioner.
6. Swadesh Kumar Bose, M.B. (Cal.), Private Practitioner.
7. Devendra Prasad Das, B.Sc. (Cal.), M.B. (Cal.), Civil Assistant Surgeon, Government of Bihar and Orissa.
8. Ghanasyam Das, M.B. (Cal.), Medical Officer, Palasbari Charitable Dispensary, Assam.
9. Nagendra Nath De, M.B. (Cal.), Bacteriologist, Calcutta Corporation.
10. Rohini Kumar De, L.M.F. (Bengal), Assistant Medical Officer, Talap Tea Estate, Assam.
11. Laxmikantrao Ramrao Deshpande, L.M. & S. (Osmania Medical College), Hyderabad, Deccan, L.C.P. & S. (Bombay), Assistant Pathologist, Osmania Hospital, Hyderabad, Deccan.
12. Henry Victor Francis, Diploma of Medical College, Calcutta, I.M.D., Assistant Surgeon, Government of India.
13. Joseph Francis Freeman, L.C.P. & S. (Bombay), I.M.D., Assistant Surgeon, Government of India.
14. Chuni Lal Ganguli, M.B. (Cal.), D.P.H. (Cal.), Private Practitioner.
15. Govindan Sambasivan, M.B., B.S. (Madras), Private Practitioner.
16. Tarak Jiban Gupta, M.B. (Cal.), Private Practitioner.
17. Kalyan Singh Makhni, L.S.M.F. (Punjab), L.T.M. (Bengal), Sub-Assistant Surgeon, Government of Punjab.
18. Gopal Narain Khanna, M.B., B.S. (Bombay), Private Practitioner.
19. Gangigunte Krishnaiah, L.M.P. (Mysore), Sub-Assistant Surgeon, Mysore Medical Service.
20. Ujagar Singh Madnawat, L.S.M.F. (U. P.), I.M.D., Sub-Assistant Surgeon, Government of India.
21. Md. Mustafa, M.B. (Cal.), Private Practitioner.
22. Mohammad Belayet Hossain, L.M.F. (Bengal), Medical Officer, District Board, Pabna.
23. Mohammad Jalal-ud-Din, M.P.L. (Punjab), L.T.M. (Bengal), Sub-Assistant Surgeon, Government of Punjab.
24. Nawab Ali, M.B. (Cal.), Assistant Surgeon, Government of Bengal.
25. Krishnan Lal Pathak, M.B., B.S. (Punjab), Private Practitioner.

26. Pooran Singh, M.B., B.S. (Punjab), Medical Officer, Rural Dispensary, Rewat, Rawalpindi.
27. Kiran Chandra Saha, L.M.F. (Bengal), Medical Officer, European Mercantile Jute Association, Charnugria.
28. Samuel Ram Singh, L.C.P.S. (Bombay), M.S.M.R. (Punjab), Sub-Assistant Surgeon, Government of Punjab.
29. Sib Chandra Sen Gupta, L.M.F. (Bengal), L.T.M. (Bengal), Resident Health Officer, Hope Tea Estate, Dooars.
30. Khun Veo Vejabhoom, Diploma in Medicine, Chulalongkorn University, Medical Officer, Military Hospital, Bangkok.
31. Hugh Scott Dalrymple Wilson, Diploma, Medical College, Madras, I.M.D., Assistant Surgeon, Government of India.
32. William John Woodhouse, L.S.M.R. (Bengal), I.M.D., Assistant Surgeon, Government of India.

BOMBAY MEDICAL COUNCIL

The following extracts from the summary of the proceedings of the meeting of the Bombay Medical Council held on 7th February, 1935, are published for information :—

The Council considered the application of Mr. K. P. Deshpande, a medical practitioner at Panvel, Kolaba District, for the registration of his name under section 7 (3) of the Bombay Medical Act, VI of 1912, and resolved that, before taking a decision, further information should be obtained from him regarding the curriculum and its length which he underwent in order to get his diploma.

The Council proceeded to consider the application of Mr. S. P. Lulla, M.B., B.S., for the restoration of his name to the Bombay Medical Register and decided that his application should not be granted yet.

The Council proceeded to ballot for the election of an executive committee for the year and, in accordance with the result of the ballot, declared the following six members elected :—

Lieutenant-Colonel Sir Jamshedji N. Duggan, Kt., C.I.E., O.B.E., D.O., etc.

Dr. D. A. D'Monte, M.D., F.C.P.S., etc.

Lieutenant-Colonel W. C. Spackman, F.R.C.S., I.M.S.

Dr. Mangaldas V. Mehta, O.B.E., F.R.C.P., etc.

The Honourable Khan Bahadur Dr. Sir Nasarvanji Choksy, Kt., C.I.E., M.D., F.C.P.S., etc.

Dr. Rajabally V. Patel, M.D., F.C.P.S.

The Council resolved that the visitors appointed last year to visit professional examinations should be continued as such and, as regards the examinations to be visited by them, the attention of the executive committee should be drawn to rule 111 of the Rules of the Council.

The Council proceeded to consider the suggestion made by the Local Government, viz, that, as the question of restricting the practice of medicine and dentistry in India to the nationals of India is a matter affecting the whole of India and therefore more appropriate for the consideration of the Government of India and the Medical Council of India, it should be taken up with those authorities, and it was resolved that this suggestion should be accepted and the Government of India and the Medical Council of India addressed accordingly.

The Council considered a proposal made by the executive committee for the appointment of a sub-committee to revise the 'warning notice' and the 'Code of Medical Ethics'. A sub-committee was appointed accordingly for the purpose.

The Council took up the re-consideration of the conduct of Mr. Ganpat Subrao Kasyapi, L.M. & S.,

medical officer, in charge municipal dispensary, Barsi, in completing and submitting on 23rd July, 1933, *post-mortem* examination reports on 3 dead bodies received by him for the purpose on the same day from the police and answering every one of the several questions laid down in the form of report regarding the different parts, internal and external of the bodies, whereas he had actually not opened any of those bodies, so that the detailed information given by him as to the internal organs of the bodies must have been untrue to his knowledge, and thus rendering himself liable to be proceeded against for infamous conduct in a professional respect.

After hearing the solicitor representing Mr. Kasyapi, the Council decided that Mr. Kasyapi had been guilty of infamous conduct in a professional respect and directed the Registrar to erase his name from the Bombay Medical Register.

The Council proceeded to consider the application of Mr. M. T. Ramchandani, M.B., B.S., for the restoration of his name to the Bombay Medical Register and decided that his request for the restoration of his name to the Register should not be granted yet.

The Council proceeded to consider the reports received from the visitors appointed to visit professional examinations for the L.C.P.S., Bombay, last year and resolved that the attention of the College of Physicians and Surgeons of Bombay should be drawn to the deficiencies indicated by the visitors.

'CARLO FORLANINI' SCHOLARSHIPS

The Italian Fascist National Federation against Tuberculosis places at the disposal of the International Union against Tuberculosis six scholarships at the 'Carlo Forlanini' Institute in Rome.

The conditions submitted are as follows :

These competitive scholarships, of a value of 3,000 liras respectively, plus board and lodging, are intended to enable foreign medical practitioners to stay at the 'Carlo Forlanini' Institute in Rome for the purpose of following a course of studies. This stage of eight months will correspond with the academic year (from 15th November to 15th July) including the usual holiday periods.

The scholars will reside at the Institute.

The scholarships will preferably be awarded to young physicians holding a good medical qualification and who are already familiar with tuberculosis problems and who wish to improve their knowledge of this branch of medicine. Licentiatees need not apply.

The kind of work undertaken at the Institute will be subject to an agreement between the director of the Institute and the candidate.

The publication expenses resulting from this work may be defrayed partly or entirely by the Institute.

The names of candidates, accompanied by particulars as to their age, qualifications and professional experience, must be forwarded to the Organizing Secretary, King George Thanksgiving (Anti-Tuberculosis) Fund, Indian Red Cross Society, 'Sherwood', Simla, W. C., so as to reach him not later than the 1st June, 1935.

INDIAN MEDICAL COUNCIL

LIEUTENANT-COLONEL R. S. TOWNSEND, M.C., Offg. I. G. C. H., U. P., has been duly nominated by the Government of the U. P. as a member of the Medical Council of India, *vice* Colonel A. H. Proctor, D.S.O., V.H.S., resigned.

Lieutenant-Colonel P. K. Tarapore has been duly nominated by the Government of Burma as a member of the Medical Council of India, *vice* Colonel C. A. Gill, K.H.S., resigned.

BACK NUMBERS FOR SALE

We have been notified that the following volumes of the *Indian Medical Gazette* are for sale. The volumes are bound and are said to be in good condition.

Librarians or others interested should apply to the

Editor who will put them into touch with the owner. He can, however, take no further responsibility in the matter, except that he is prepared to examine volumes and to express an opinion regarding their condition on behalf of foreign purchasers.

Volumes I to LXIII (1915-1928) inclusive.

Passive and Active Immunization against Measles

By LAWSON WILKINS, M.D.

(Abstracted from the *International Clinics*, Vol. III, 1931, p. 267, J. B. Lippincott Company, Philadelphia)

ETIOLOGY OF MEASLES

THE cause of measles is not yet definitely known. Many organisms of various types have been described as the etiological agent but none has withstood the tests of critical investigation. In recent years Caronia has attributed measles to a minute Gram-negative filter-passing coccus, and Tuncliff and Ferry and Fisher to specific green-producing streptococci. There is considerable evidence against any of these organisms. Most workers now believe that measles is due to a filterable virus. Attempts to transmit the disease to domestic and most laboratory animals have not been entirely conclusive, in as much as the incubation period and symptomatology have not been entirely characteristic. On the other hand, measles has definitely been transmitted to man and to monkeys by the injection of small amounts of blood and by nasopharyngeal secretions. Blood used for inoculation has shown no bacterial growth when cultured on various media. Blake and Trask have transmitted the disease to monkeys by bacteria-free, filtered, nasopharyngeal washings and were able to pass it from monkey to monkey. Degkwitz and Harrison claim to have grown the virus in culture in symbiosis with the diplococcus of Tuncliff. The inoculation of monkeys with a bacteria-free filtrate of the cultures caused a febrile reaction but not a typical rash and rendered the monkeys immune to subsequent infection with measles.

PASSIVE IMMUNIZATION

Convalescent serum—Although convalescent blood serum was used for the treatment of measles by Weisbecker in 1895, Conci was apparently the first to employ it for immunization in 1901. In 1918 Nicolle and Conseil published their results in the protection of exposed susceptibles and in the same year Richardson and Connor used it to control a hospital epidemic in Providence, R. I., and Park and Zingher tried the method but did not publish their results until 1924. After Degkwitz, in 1920, described his experience in 700 cases, the method soon became used more generally and since this time a voluminous literature has appeared.

Debre and Joannon and others have shown that in patients convalescent from measles the maximal concentration of antibodies is reached from the seventh to the tenth day after the fall of the temperature. After this there is a gradual decline in the antibody strength of the blood but a point is reached at which the strength remains comparatively constant—perhaps for the rest of life. It is, therefore, best to prepare the serum from the blood of a patient taken the seventh to tenth day after defervescence. The donor should be free of tuberculosis and have a negative

Wassermann test and the blood should be cultured for sterility. If desired, the serum may be passed through a Berkfeld filter. The serum may be preserved with 0.2 to 0.5 per cent phenol, although this renders the serum turbid. Recently Merthiolate in a concentration of 1:10,000 has been used as a preservative and causes no clouding. Kept in a refrigerator, it retains its potency for at least nine months and probably for two years.

If the serum is injected intramuscularly in doses of 35 cc to 10 cc during the first five or six days after exposure, it will completely protect a large majority of children and partially protect nearly all the others. When the serum is given between the sixth and ninth day of the incubation period, complete protection is not afforded but the disease occurs in a modified or attenuated form. After the ninth day the serum has no effect. The attenuated form of measles presents a striking contrast to the usual form. In some cases nothing is noticed except a few scattered pinkish macules. Usually the incubation period is prolonged, often to three weeks or more. The temperature usually does not exceed 100°F to 101.5°F. The rash is scanty and resembles that of German measles. The catarrhal symptoms are absent or mild. Koplik spots are not found. Secondary complications do not occur.

Adult immune serum—The difficulty of procuring sufficient quantities of convalescent measles serum led investigators to try the value of the serum or citrated whole blood of adults who had had measles in earlier life. The fact that second attacks of measles are comparatively rare indicates that immune bodies persist in most individuals throughout life. Degkwitz in 1920 was the first to attempt passive immunization to measles by the injection of the serum of adults who had previously had the disease. Since then there have been numerous reports on the subject. Relatively large doses of adult serum—20 cc to 40 cc—are usually required to afford protection. A review of the literature shows that even with these doses favorable results are not obtained as uniformly as with convalescent serum.

Relative dosage of convalescent and of adult serum—It is difficult to state the exact dosage of convalescent serum or of adult serum which should be given to prevent or to attenuate measles. This difficulty arises because the following variables must be taken into consideration: (1) the age and size of the child, (2) the day of incubation, (3) the intensity of exposure, (4) the potency of the serum. It is stated that attenuation rather than prevention may be attained by giving either a small dose of serum early in the incubation period or a larger dose late in the incubation period. However, the latter method is more reliable and is probably preferable as offering a means of establishing a more lasting immunity. A wide variation in dosage has been recommended by different workers; for example, all the way from 25 cc. to 10 cc. of convalescent serum and from 10 cc to 40 cc of adult serum have been employed during the first five days of incubation to secure complete protection. The following table gives the

reviewer's opinion of the dosage which can be expected to yield fairly uniform results :

		Days of incubation	
		1-5 days	6-8 days
<i>For complete protection.</i>			
Convalescent serum	5-10 c.c.	Protection usually not secured.	
Adult serum ..	30-40 c.c.	Protection usually not secured.	
<i>For modified attacks</i>			
Convalescent serum	2-4 c.c.	4-10 c.c.	
Adult serum ..	10-20 c.c.	20-40 c.c.	

The variation in results would be largely overcome if there were a simple and practical method for the standardization of the potency of the serum. Such a method would be of great value especially when one is compelled to use adult serum or serum stored for a long time. It is probable that convalescent serum is comparatively uniform in its potency. However, the diversity of results obtained with adult serum by different workers indicates that it may vary considerably in its antibody content. The writer has had the opportunity to observe this on a number of occasions. He has been able to afford complete protection with as little as 8 c.c. of his own serum and yet at times has failed to obtain any modification with 30 c.c. of a parent's serum. The variability of the concentration of immune bodies in the serum of different adults can to some extent be overcome by using pooled serum from a large number of individuals. When convalescent serum is not available it is therefore preferable to use such pooled adult serum rather than the blood of a parent. If a large batch of serum is used in successive cases, the physician becomes familiar with its potency from the results obtained and can judge the dose accordingly with considerable accuracy.

DURATION OF IMMUNITY AFTER SERO-PREVENTION AND SERO-ATTENUATION

The injection of immune serum at an early stage of the incubation period in sufficient quantities to entirely prevent measles confers merely a temporary passive immunity. As in the case of other infections, passive immunity probably lasts only two or three weeks, or at the most several months. On the other hand, the occurrence of a modified or attenuated form of measles, after the injection of smaller amounts of serum, may give rise to a more lasting form of active immunity. As yet there are not sufficient data to determine how complete and how lasting is the protection afforded by such attenuated attacks. It is entirely possible that immunity may be established for life especially if it is reinforced by the repeated exposure of the patient to contagion. Certainly the children who have had attenuated measles during one epidemic are rarely if ever observed to contract the disease a second time during the same epidemic. It is of importance to follow large groups of such children in subsequent epidemics to determine whether the immunity persists. Debre states that he has followed several hundred children in successive epidemics. Many of the children who had attacks attenuated by serum in one epidemic were intimately exposed to measles in subsequent epidemics without becoming infected; whereas those whose attacks had previously been entirely prevented contracted the disease. Debre also points out that the degree of immunity varies with the extent of attenuation which has been produced. When the attenuated attack has been very mild, the immunity is only partial and the patient may subsequently have another mild attack.

The practical application of sero-prevention and sero-attenuation.—Sero-prevention and sero-attenuation each has its own place during a measles epidemic. In children's hospitals the accidental admission of an unrecognized case of measles was formerly followed

by successive crops of contact infections over periods of weeks or months, necessitating periods of quarantine and restriction of admissions. The hospital infections were not only embarrassing to the administration but were exceedingly dangerous to young infants and delicate or tuberculous children. Now every effort is made to prevent contact infections by the early administration of sufficiently large doses of convalescent serum to all patients who may have been exposed in any way. Since measles is so highly infectious, it is usually necessary to inject all the susceptible children in whole wards or in the entire hospital. In spite of the attempt to completely prevent infection, some attenuated forms of measles usually occur which are harmless but nevertheless serve as sources of further infection. Likewise, the passive immunity which has been conferred on the other children may be lost after three or four weeks. Therefore, as long as a source of infection is smouldering in the form of any attenuated cases it is necessary to inject all new admissions with serum and to reinject the other patients every three or four weeks.

In child-caring institutions such as orphanages, the situation is similar. However, if there is a relatively permanent instead of a transient population, it may be advisable to purposely expose all the children to the infection and to give the serum in attenuating rather than preventive doses. In this way a comparatively lasting immunity is established and the epidemic will have completed its course in the institution within a relatively short period.

Measles serum has its widest sphere of usefulness in the hands of the family physician and he should consider it his duty to employ it extensively. Measles is especially a family contagion. Where there are a number of children in a family, an older child of school age usually becomes infected outside the home. As a rule the parents are unaware of his exposure until the disease is under way and it is too late to give serum. Fortunately, in the older child the disease is less apt to be dangerous. If there are younger brothers and sisters, they are practically certain to contract the disease and may develop into dangerous cases. The family physician usually has the opportunity to give serum either to prevent or to attenuate the infection in these younger children. Except in the case of very delicate infants, it is preferable to regulate the dose so as to permit an attenuated infection to occur. If the disease is entirely prevented, the immunity may be very transient and after a few weeks, the child may contract the disease from a subsequent exposure in the same epidemic. The serum of a convalescent, if available, is preferable to any other. If convalescent serum cannot be obtained, the serum of physicians or nurses who have been in frequent contact with measles cases is probably the next most reliable. If neither is available, the pooled serum from a number of adults, who have had the disease, may be used. When no other serum can be obtained, the serum or citrated whole blood of one or both parents may be used, although the results are subject to greater variability than with the other methods.

In a few communities the health departments have undertaken the collection and preparation of convalescent or pooled adult serum and have made the serum available to physicians who desire it. In most communities, however, the health department has considered that too great a task, and it has been necessary for the practitioners to collect their own serum. Adults who contract the disease are eagerly sought as donors of large amounts of serum. Parents who have witnessed the benefit to their younger children from attenuating doses of serum are usually glad to permit the physicians to take 60 or 100 c.c. of blood from a convalescent older child to be used for his future cases. Laboratories are usually available for the separation and sterile bottling of the serum. However, the inconvenience of collecting repeated specimens of blood to some extent stands in the way of the more

general use of serum by the busy practitioners during an epidemic. It is to be hoped that some method of reactivation of adult serum or the preparation of immune substances from the human placenta may eventually provide an abundant and easily available source of measles antibody. A method for the accurate standardization of such preparations is highly desirable.

ACTIVE IMMUNIZATION AGAINST MEASLES

The methods which have been discussed previously have been concerned with the injection of immune bodies into children who have been accidentally exposed to measles and are already in the incubation period. It is apparent that if these methods were generally applied, especially to children under three years of age, they would reduce materially the mortality from measles. They could not be expected to affect radically the morbidity of measles or to offer any hope for the eradication of the disease. Unless some method can be devised to confer an active and permanent immunity on all children, measles will continue to recur in great epidemics, and many children will contract the disease without knowledge of their exposure, so that they cannot be given the benefit of serum during the incubation period.

As early as 1758, inspired by the practice of the inoculation of smallpox then in vogue, Francis Home undertook the inoculation of children with measles by applying to scarified areas of skin the blood taken from measles patients at the height of the disease. He claimed that in this way he produced measles in a mild form and that the children were afterwards immune to infection. As the incubation period was said to be only two days and the possibility of natural infection was not entirely excluded, the work of Home is open to question. In recent years, however, a number of methods for active immunization against measles have been suggested and are worthy of further consideration.

Active immunization by purposely infecting with measles and attenuating with serum.—As already pointed out, the sero-attenuation of measles is really a method which permits an active immunity of greater or less degree to develop as a result of a mild infection. It is applicable, however, only when one has definite knowledge of the exposure of the patient and even then one cannot be certain that the disease is being incubated. During a widespread epidemic the school children are almost certain to become accidentally infected. It would seem justifiable to purposely infect them by intimate contact with patients in the active stage of the disease in order that one might know the exact day of incubation and administer an attenuating dose of serum at the proper time. If the protective potency of serum could be standardized with sufficient accuracy, one would not hesitate to do this, provided the child's parents were intelligent and co-operative.

Different workers have actually employed a number of methods of infecting children and have simultaneously attenuated the infection with immune serum. Richardson and Connor in 1919 inoculated three children with nasal secretions of active cases and simultaneously administered immune serum. Only one child developed a mild form of measles. Zingher in 1924 produced modified measles by first swabbing the mucosa with nasal secretion and later injecting the proper amount of convalescent serum. Copeman (1927) recommends the injection of immune serum into the unaffected subject followed by an inoculation with the virus. Instead of employing the nasopharyngeal secretions as the infecting agent, Nicolle and Conseil (1923) used blood from an acute measles case. They recommended the administration of convalescent serum followed twenty-four hours later by the injection of 1 c.c. of measles blood.

Active immunization by the inoculation of infants during the period of inherited immunity.—It is generally recognized that infants under five months of

age are relatively immune to measles provided that their mothers have ever had the disease. Hermann believes that, if infants are inoculated with measles virus during this period of inherited immunity, they will develop an active and permanent immunity to the disease. Between 1914 and 1922 he inoculated 165 healthy infants between four and five months of age according to the following technique: The nasal mucus discharge of measles patients free from other diseases is taken from twenty-four to forty-eight hours before the appearance of the eruption, mixed with a small quantity of saline solution, and bacteria and other extraneous material separated by centrifugalization. A little tricesol is added as a preservative (1); and a few drops of the solution are then applied to the nasal mucous membrane of the infant to be immunized. The best results were obtained when there was some reaction following inoculation, such as a slight rise of temperature from the eighth to the sixteenth day, or a few spots on the body. Of one hundred and sixty-five infants inoculated none showed any unfavourable effects. Seventy-five of the infants were followed from four to eight years and only five or these contracted measles. Of the remaining seventy, forty-five had been exposed directly to measles infection in the same family or house. In eighty-four of the one hundred and sixty-five there was a definite reaction following inoculation consisting of a rise of temperature, with or without spots on the face and body, and none of these eighty-four cases developed the disease.

Active immunization by the injection of small amounts of virulent measles blood.—Since it had been shown that the blood of a measles patient at the beginning of the rash contains the infectious agent, Hiraishi and Okamoto (1921) attempted to induce acquired immunity to measles in forty-four healthy children by injecting small amounts of blood taken from patients just before the appearance of the rash. The doses varied from 0.0001 to 0.005 c.c. The children were later tested for immunity by exposing them to measles, smearing their throats with infectious measles secretions, or injecting large amounts of measles blood. The experiment was apparently not successful as twenty-nine of the children developed measles within the next nine weeks.

Debre and his associates have studied this method in more detail. In non-immune children two to five years of age, the subcutaneous injection of 1/800 (0.00125) c.c. of virulent blood causes an elevation of temperature of 100.0°F. to 100.4°F. between the seventh and tenth day, and an increase in leucocytes followed by a leucopenia. There are no other symptoms. However when an original dose of 1/400 (0.0025) c.c. of blood is injected, there appears on the eighth day a slight catarrh with a buccal enanthem and occasionally Koplik spots, and on the following day there is a morbilliform eruption with a slight rise of temperature to about 100.4°F. All these symptoms disappear in twenty-four to forty-eight hours without any constitutional disturbance. The characteristic blood picture is observed. If 1/800 c.c. of virulent blood is first injected, the subsequent injection of 1/400 c.c. does not cause the slight reaction. By rapidly increasing the dose injected, as much as 0.5 c.c. may be given without clinical reaction. Prior to 1928, Debre and his associates had injected 1,000 children with two doses of virulent blood in an attempt to produce active immunity. In children two to five years of age the first dose was 1/800 c.c. and the second 1/400 c.c.; in children five to ten years of age, 1/600 c.c. and 1/400 c.c. No bad results were obtained. Debre has not yet reported on the immunizing value of the method as judged by the response of the children to subsequent exposures to measles.

Comment on the present status of active immunization.—The active immunization of children against measles remains an intriguing problem. At present when children are accidentally exposed, if one has

knowledge of the exposure, it is preferable to administer serum in such a way as to secure attenuation rather than prevention of the disease, in the hope of producing more or less lasting, active immunity. In the course of large epidemics, school children are so prone to contract the disease from unknown accidental exposures, that it would seem justifiable to purposely infect them in order that one might know the exact time of infection and attenuate the disease with serum at the proper date during the incubation period. If highly effective serum of standardized potency were available this method would be generally practical. It seems doubtful whether infection by swabbing with infectious nasal secretions or by the injecting of virulent blood would offer any advantages over the natural method of infection by bringing the subject into intimate contact with a patient in the acute stage of measles. Objection to the method may be raised because of the danger of transmitting other intercurrent infections, but this objection is outweighed by the greater risk of the unrecognized accidental exposure. Of course, the prejudice of uninformed parents will probably stand in the way of the widespread application of such a method. Harmann's proposal to inoculate young infants in the stage of inherited immunity is open to more serious criticisms. The dangers of transmitting colds or influenzal infections to infants of tender age would be great. Furthermore, the results with diphtheria immunization indicate that it is difficult to produce permanent active immunity by inoculating during the period of inherited immunity. The attempts to produce immunity by the injection of sub-clinical doses of infectious measles blood is of great interest but so far there is not sufficient data to judge the success of the method.

On the basis of our present knowledge, every effort should be made to attenuate or prevent measles by immune serum in children under the age of three years, the period when the disease has a high mortality. In older children the disease should be attenuated whenever possible, and with the co-operation of intelligent parents purposeful infection and attenuation are justifiable. Whether any practical method for the general active immunization of all children can be developed is open to question. The value of the herd immunity caused by childhood infections is amply demonstrated by the disastrous results of the introduction of measles into non-immune populations, as in the Faroe Islands and elsewhere. Unless a method of active immunization could be relied upon to afford effectual and permanent protection one would hesitate to employ it to eradicate measles from a community.

Changing Concepts of Nutrition

By JAMES S. McLESTER, M.D.

(From the *Journal of the American Medical Association*, Vol. 103, 11th August, 1934, p. 383)

THE day was when, in order properly to nourish the sick person, the physician told him what he must not eat; now, he is told what he must eat. This changing concept of nutrition marks a great advance in clinical medicine.

Until a decade ago, nutrition was the stepchild of medicine. True, for generations this science has been constantly advanced by a long line of brilliant investigators from Lavoisier to Graham Lusk, but physicians have been slow to give this knowledge practical application. This lack of interest was due in no small measure, I believe, to the semicharlatanism and wild faddism which have always flourished in this field and which have led many conservative physicians to give it a wide berth. Now a reversal of feeling has taken place. The great discoveries of recent years have excited the interest of everyone, laymen and physicians alike, and to-day medical men are keenly alive to the vastly important part which nutrition plays in the prevention and treatment of disease; a radical

change in the conception of the nutritive needs of the sick person has come about. This change is explained, I believe, by the order in which, in the evolution of modern medicine, the basic sciences have developed, cellular pathology coming early and present-day physiology late. Formerly, in planning the patient's food, physicians thought solely in terms of the local pathologic condition, of the harm they might do some impaired organ; now they think chiefly in terms of general physiology, of the good they can do the patient as a whole. This transition is signally characteristic of modern thought in nutrition.

All of this was foreshadowed twenty-five years ago by a complete about face in the treatment of typhoid. As an intern I saw the soldiers ill with this disease who returned in large numbers from the Spanish-American War, and two things stand forth in my memory: the miserably small amounts of food that were given these patients, and their desperately ill state. To-day one sees a different typhoid. Now the patient is seldom very ill; the carphology and subsultus tendinum of those earlier days is a thing of the past, as is the muttering delirium, the distressing abdominal distension and the so-called toxæmia, all because Warren Coleman demonstrated that the patient with typhoid must be adequately nourished. No longer do physicians think chiefly of the pathologic changes in the small intestine but rather of the nutrition of the patient as a whole. To-day he is given much more abundant food of relatively wide variety, and as a rule he gets well.

Witness the change that has come about in the treatment of gastric ulcer. The method that long prevailed was the semistarvation plan of von Leube, until finally Lenhartz showed that the cure of almost anything is made more difficult by starvation and pointed out the fallacy of such rigid food restriction. The regimen which he instituted and which was revised for the American stomach by Sippy is of value not merely because the more abundant food has a direct influence on the stomach but also because it keeps the patient in something like nutritive equilibrium. It promotes repair.

A grievous error of the past was the dietary limitation imposed on the patient with Bright's disease. In the treatment of all forms of nephritis the physician had in mind but one object, that of sparing the kidney, and reasoned that this could best be accomplished by drastic restriction of the protein intake. Because of limited vision the effects on the kidney of the degradation products of protein metabolism were feared, and in the interest in the local changes the patient himself was forgotten. Physicians entirely overlooked the fact that food proteins which are used for replacement purposes are not degraded to their end-products and therefore can in no wise increase the burden on the kidney and, what is still more important, failed to realize that protein loss plus protein starvation must of necessity lead to a depletion of body proteins and thus eventually to a state of chronic inanition, which in turn retards all recovery.

If recovery is to be promoted, protein loss must be made good. The truth of this was first seen in the striking results obtained by Epstein when his nephrosis patients, with their heavy albuminuria, were fed large amounts of protein. Later this became still more evident through the observations of van Slyke and his associates, who found that if the plasma protein deficit of glomerular nephritis is allowed to persist the patients fare badly, while, on the other hand, if the albumin loss is made good and the blood proteins are maintained at approximately the normal level, the patients as a rule go on to complete recovery. The accuracy of these observations has been abundantly attested by McCann in the excellent results achieved when he prescribed large amounts of protein for patients with glomerular nephritis. In some of McCann's patients the improvement was graphic. From such experiences it has been learned not only

that rigid protein restriction in nephritis is bad but that if the patient is to be given the best opportunity for recovery he must be adequately nourished, and that of paramount importance is a liberal, sometimes a large, intake of protein. Here, too, the medical profession has advanced from a consideration of local pathologic change to one of general physiologic function.

In the same category until recently was the patient with vascular hypertension. He was told that he must eat no meat, no eggs. I have no doubt that the resulting protein starvation imposed an additional handicap on many persons already suffering from heavy disabilities and that much unnecessary semi-invalidism resulted. From a better understanding of nutrition it is now known that instead of this one-sided diet the persons so handicapped must have a well-balanced ration, never excessive, but never lacking in any essential, such a diet as is best calculated to preserve the greatest degree of vigour for the longest period of years.

Even more recent is the change that has come about in the conception of the nutritive needs of the patient with diabetes. The earlier understanding of this disease was that it was merely a failure of carbohydrate utilization. It was thought of only in terms of carbohydrate metabolism and the patient's food was restricted accordingly. Then came insulin; this agent has helped enormously, and while it has not solved the riddle of diabetes it has pointed the way to one important truth, that is, that the entire animal economy, not merely a single metabolic fault, must be considered. In providing nourishment for the diabetic patient it has been learned that he must get adequate amounts of every class of food, particularly of carbohydrate, the very foodstuff that was formerly restricted with such rigour.

Even in tuberculosis, views have materially changed. The ability of the patient to store fat was once thought to be the best criterion of progress, and that to bring about a condition of obesity or near obesity was the acme of good treatment. Now it is known that such a condition imposes a real handicap. It is evident from a nutritional standpoint that the greatest good for the tuberculous patient can be accomplished by a diet that is liberal but not too liberal, that is, a diet that keeps him in a state of nutritive equilibrium and approximately at his ideal weight. This, infinitely more than a condition of overweight, encourages recovery.

In chronic arthritis every variation of dietary restriction has been played on, and almost everything, at one time or another, has come under the ban. Proteins were restricted because they increase the production of uric acid; fruit and tomatoes were forbidden, strange to say, because they contain acids; and sugars and starches were limited because a few students of arthritis have concluded that lowered dextrose tolerance is a salient feature of these disorders. No satisfactory clinical evidence, however, has yet been presented to show that such restrictions, even of carbohydrate, influence the course of arthritis. The feeling is gaining ground that, except for reduction of weight in the obese, most can be accomplished in a nutritive way for arthritic patients by warning against one-sided diets and by prescribing a fairly liberal ration which carries all nutritive essentials. It is coming to be realized that these unfortunate patients are destined to be sick a long time and that they should be permitted a ration which best insures against nutritive failure.

Even the nutritive needs of infancy and early childhood are to-day viewed with a much broader understanding. Those practitioners who were taught the elaborate milk formulas of thirty years ago marvel at the wide variety of foods given infants to-day, spinach, carrots, beets, tomatoes, scraped beef, even sweet potatoes. They take almost anything and thrive.

I am tempted to hazard the prediction that this shift in the concepts of nutrition will extend to the obstetric practice of the future. That school of thought which restricts the protein quota of the pregnant woman's ration for fear of damaging the liver and thus producing eclampsia is, I believe, in error. And, too, those obstetricians who materially restrict all food in pregnancy in the effort to limit the size of the offspring and thus make labour easier are likewise, I fear, in error. During pregnancy the woman needs, more than at any other period of her life, an abundant diet which provides in adequate amounts all necessary food factors, not only carbohydrate and fat but proteins, vitamins and minerals as well. To deny her this, even in small degree, is to court disaster.

In conclusion I would call attention to the fact that these changing concepts of nutrition are not the result of vacillation or of an uncertain drift of opinion. Far from it. They express the broader understanding of man's nutritive needs that has come with the discoveries of recent years and represent the well-considered application of knowledge gained, little by little, from painstaking research and careful clinical observation. This is the way of progress.

Control of Measles

By G. HALE, M.B. (Camb.)

(Abstracted from the *Lancet*, 1st December, 1934, p. 1222)

DURING the latter part of the biennial epidemic of measles in 1931-32, the wards of the Victoria Hospital for Children were kept open by the use of either convalescent or adult serum, whichever could be obtained. There were three wards each of 18 beds, and the period covered was February to July. Susceptible children who came in contact with measles while in the wards received an intramuscular injection of serum within the first five days of incubation, complete protection being the objective. Susceptible children known to be contacts were not admitted.

A sliding scale of dosage was used—a minimum of 5 c.cm., plus 1 c.cm. for each year of life—but in a few cases it was not strictly followed. As time went on it became increasingly difficult to obtain either adult or convalescent serum, and in two cases the serum of parents was used.

The parents of the contact were sent for and the position was explained to them. If they had had measles about 50 c.cm. of blood was withdrawn from one of them, and as soon as the serum had separated from the clot an injection was given to the child. In deciding whether to take blood from one parent rather than the other, preference was given to the one who had had the more recent attack. If he or she had had two or more attacks this was taken as a sign of poor immunity. General physical fitness was taken into account, and other things being equal the younger parent was preferred. No Wassermann or other test was performed, but it was explained that syphilis contracted after the birth of the child might be transmitted by the injection. If any parental serum was left after the child had had the injection, a Wassermann test was done and it was put into ampoules for later use. In the two cases treated, the dosage used was as then advised by the public health department of the London County Council. Up to the age of three years it was 10 c.cm.; from three years onwards the number of cubic centimetres to be given was calculated by multiplying the age, in years, by four.

There seems to be no reason, in the ordinary way, why parental serum should differ at all from mixed adult serum; though presumably the results are not likely to be so uniformly good.

The value of protecting susceptible cases in hospital from measles is obvious from the accompanying table,

and the method is widely practised. The principal objections to its application in private practice are: (1) that few children are taken to the doctor during the incubation period; and (2) that the serum is hard to get. The first of these difficulties can only be overcome by wider knowledge of preventive medicine among the public, or conceivably by compulsory notification of all cases and the tracing of contacts. The second is really no difficulty at all, provided one of the child's parents has had measles. It should not even be necessary to prepare the serum, for a direct injection of whole blood from the parent should be quite as effective as an injection of serum, provided allowance is made for the volume of the clot in estimating the dose.

Date in 1932	Sex	Age	Dose in c.cm.	Day of inc.	Result
<i>Convalescent measles serum</i>					
March 19	M.	9 yrs.	10	4	Protected.
May 6	M.	3 "	8	5	"
"	F.	6 "	11	5	"
"	F.	6 "	11	5	"
"	M.	2 m'ths.	5	5	"
"	F.	20 "	5	5	"
"	M.	3 "	5	5	"
May 14	M.	21 "	5	2	Measles developed after discharge on 31st May; attack said not to be severe.
May 18	F.	11 "	3	2	Protected.
<i>Adult measles serum</i>					
April 20	M.	9 yrs.	13	4	Protected. Had had 10 c.cm. convalescent serum on 19th March.
"	F.	5 "	11	4	Died of T.B. meningitis on 23rd April.
"	F.	5 "	10	4	Protected.
"	M.	7 wks.	5	4	"
"	M.	5 m'ths.	5	4	"
"	F.	11 yrs.	16	4	"
"	F.	4 "	9	4	"
"	F.	wks.	5	4	Died of congenital syphilis on 21st April.
"	F.	7 yrs.	12	4	Protected.
"	F.	4 "	5	4	"
"	F.	18 m'ths.	5	4	Developed measles on 2nd May. Rash and fever only lasted 24 hours. No Koplik's spots.
<i>Parental measles serum</i>					
May 14	F.	2 yrs.	10	2	Protected. Pertussis, 29th May.
"	F.	4 "	15	2	Measles, 16th May (note date). Fever lasted 3 days; some bronchitis.

Inc. = incubation.

In private practice there is no object in protecting all measles contacts and leaving them susceptible again in a few weeks, but there is every reason to modify the attack by giving the injection between the sixth and the ninth day of incubation, thereby insuring against complications, severe illness, or even death.

The Place of Phrenicectomy in the Treatment of Pulmonary Tuberculosis

By J. GRAVESEN, M.D.

(Abstracted from the *British Journal of Tuberculosis*, Vol. XXIX, January 1935, p. 12)

AFTER certain exclusions the material for true statistical analysis is reduced to 153 cases.

It is now found that a permanent positive result has been obtained in 55 of these, the 98 remaining cases showing no positive indications of lasting beneficial results.

The effective results.—These figures mean that only a little more than one-third of the cases have derived lasting benefit from the operation. This, far from being reassuring, leads to an unfavourable comparison with the results obtained by other forms of surgical treatment after a similar period of observation.

A more minute study of the 55 cases with positive results further reduces the apparent efficacy of the operation. Eleven of the patients had already shown such marked improvement before the phrenicectomy was performed that one feels uncertain about the benefit accruing from the operation. In another 17 cases the patients continued to expectorate tubercle bacilli, and the whole question of improvement therefore became rather debatable.

This leaves only 27 cases where we have any right to say that the patients were healed as the result of the phrenic operation. An individual study of these 27 cases shows that they represent the most localized and the least serious affections out of the total material examined. When it is remembered that all of these patients had been living under sanatorium regime both before and after the operation, and that many of them had received other forms of treatment (e.g., sanocrysin, light treatment, etc.), one seems justified in thinking that it was in conjunction with these other methods, rather than by the evulsion itself, that the beneficial results had been obtained.

These facts verify the impression which has been steadily gaining ground in our minds during our twelve years' experience of the phrenicectomy—namely, that the actual efficacy of the operation has been greatly exaggerated by many who have written about it.

This is not meant to be a wholesale condemnation of the phrenic operation. Where definite indications are found, we believe some good may be achieved by phrenicectomy. What we wish to protest against is its indiscriminate use even where no special indications are present.

A further examination of the 'negative' group provides a forcible argument in support of this warning.

The non-effective results.—Here, too, the conclusions are the result of our deliberate and unprejudiced judgment of the 98 cases, with no lasting effect: 26 of them must be left out of consideration, as they had already shown very malignant or complicated developments. The operation was used as a last resort: it would therefore be unfair to debit the phrenicectomy with the unfavourable result. In another 18 cases the operation had been performed elsewhere before the patients were admitted here; they came for further help by surgical or other forms of treatment. As these cases represent a particular group of non-effective results, they should not be used as basis for an unfavourable estimate of phrenicectomy.

But the remaining 54 cases are a heavy weight on the debit side of this method. In all these cases the operation has reduced the respiratory function of the affected lung to a considerable degree, without any compensatory result. This fact alone deserves much more attention than has been given to it by many who have written about it.

Moreover, it must be remembered that in most cases it is the healthy lower lobe which is disturbed in its function, while the affected apical area shows

and the method is widely practised. The first of some cough may remain, and come by wider minims of the tincture, for a child among the pile (gr. 1/20) are both useful remedies. fication of ant to insure complete recovery, and a second ; ant may be required to achieve this. the most cases the course of the disease is quite straightforward but in young infants considerable areas of pulmonary collapse may follow obstruction of one of the larger bronchi by secretions. In an endeavour to prevent this, babies with bronchitis should not be allowed to remain too long in one position, and it is well to take them out of their cots and nurse them from time to time. Bottle feeds should always be given on the lap. The secretions may be so tenacious that feeble infants are unable to dislodge them and are in danger of respiratory failure. When such a collapse occurs the baby should be rapidly transferred to a mustard bath (one ounce of mustard to 1 gallon of water at 100°F.), and given brandy and other stimulants. An injection of strychnine (gr. 1/400) with adrenaline (m ii of a 1 in 1,000 solution), and Curschmann's solution (m. v) is suitable for a child of three months and can be repeated at four-hourly intervals.

BRONCHO-PNEUMONIA

Treatment.—Nursing is of primary importance, and the doctor who feels that he must do something, often does too much. Excessive medication may easily provoke vomiting and diarrhoea. The child is best nursed propped up in bed, but his position should be frequently changed. The room should be well ventilated, and in warm weather the child is best placed on a balcony, but it may be difficult to make the parents approve of this treatment. Coverings should not be too heavy; a two-piece pneumonia jacket, tying at the sides, and over it a light flannel nightshirt with long sleeves, loosely fastened at the back, will cause the least disturbance. Warm antiphlogistine poultices to allay pain, or cold compresses to encourage aeration of the lungs and avoid pulmonary collapse, may be applied to the back and kept in position by a loose many-tailed bandage. Proper hygiene of the nasal passages is also necessary. They should be kept free by alkaline irrigation and some antiseptic nasal oil. Glycerine and borax keeps the tongue clean and moist. The child should be encouraged to drink plenty of water or sweetened fruit juices. Food should be light, nourishing, and given at two-hourly

intervals. Feeds known to have suited the infant before the illness should be continued. Breast feeding should not be interrupted, and if suckling appears to exhaust the child too much, some of the milk will have to be drawn off and given with a spoon. In older children a distended abdomen must be met by light diet for a few days: whey, peptonized milk, veal tea, jellies, fruit juices, and the like. Daily evacuation of the bowels must be attended to. Flatulence may be severe in infants and is best treated by a simple rectal washout or turpentine enema.

Drugs should not be given to reduce the temperature. Should it rise about 105°F., tepid sponging is the correct treatment. Tepid sponging may also soothe a restless child to sleep. A dose of brandy often has an equal effect, but in bad cases during the early stages, opium in the form of Dover's powder may be required. Wheezy breathing, or an associated 'croup', is greatly relieved by a steam tent, as described above. Continuous oxygen and carbon dioxide (5 per cent) tends to diminish a spasmodic cough, but its greatest use is in the presence of cyanosis. To be effective it must be given by the nasal catheter, the gas being bubbled through warm water, contained in a Woulfe's bottle, at the rate of 20 to 30 bubbles a minute. A little 2 per cent cocaine ointment on the catheter may be required in older children. Oxygen through a funnel is ineffective and merely a placebo for the relatives. The early stages of cardiac failure can be treated with small doses of digitalis—2 to 3 minims of the tincture six-hourly for a child of two years, but some authorities have no faith in this. If the child shows signs of collapse, stimulants will be required, such as brandy by the mouth and injections of camphor and ether (Curschmann's solution, minims 5 to 10); these can be alternated every four hours. Strychnine, adrenaline or coramine are other useful stimulants. Alkaline expectorants should be given when the bronchial secretions are sticky, and belladonna may give great relief should they become excessive.

Specific serum therapy has not been attended with sufficient success in children with broncho-pneumonia to warrant its routine use. Incomplete expansion of part of the lung from unresolved pneumonia is best treated by oxygen and carbon dioxide (7 per cent) inhalations from a gas bag. Strict attention must be paid to proper convalescence, and if there is any residual inflammation the child should be sent to the seaside.

Reviews

DISEASES OF CHILDREN. Third Edition. With contributions by thirty-six authors. Edited by H. Thursfield, D.M. (Oxon.), M.A., F.R.C.P., and D. Paterson, M.D. (Edn.), F.R.C.P. 1934. Edward Arnold and Company, London. Pp. xi plus 1152, with 277 figures in the text. Price, 50s.

THIS book has already established itself as the standard book on paediatrics for students in the British medical schools. The book has now reached its third edition, and it is still edited by one of the original editors, Hugh Thursfield. Furthermore, Sir Archibald Garrod still remains as a contributor. Other contributors have dropped out and new ones have been added. There are entirely new chapters on heredity, blood transfusion, orthodontic treatment, the newly-born infant, diseases of the accessory nasal sinuses and the ear, the lipoidoses, acetonæmia, cystoscopy and pyelography, rheumatism, allergy and tuberculosis.

The book has retained its original arrangement, but every chapter has been completely recast and much

new matter, including a number of illustrations, has been added, since the last edition five years ago.

Each one of the thirty-six contributors is a specialist attached to one or more of the leading London general or children's hospitals. This fact alone leaves the reviewer little chance for criticizing the individual chapters. In each a very complete account of the subject is given; our most important reaction was surprise that it was possible to achieve such completeness and yet limit the work to a single volume. The new chapter on heredity is a very welcome addition; it forms an excellent opening for a book on paediatrics.

We must admit to being a little disappointed in the section on the classification of anæmias. It struck us as being very confusing. We do not understand what the writer means by the statement that ' hæmolytic anæmias include not only those diseases in which there is an active destruction of the erythrocytes, but also those in which the hæmopoietic centres are so damaged that they can no longer produce the essential constituents of the circulating

blood in sufficient quantity'. Why should aplastic anemias be classified as haemolytic?

Tropical diseases are wisely avoided; wisely, unless the editors were prepared to obtain the collaboration of a writer with actual experience in tropical diseases. Malaria is the only tropical disease that we noticed in the book. We see that the writer has emphasized the fact that children require relatively large doses of quinine; they also stand them well. Plasmochin is advocated for 'prophylactic' use. We do not know exactly what the writer means by 'prophylactic', but we rather suspect that he means something that plasmochin does not do. It is a 'prophylactic' only in the sense that given to a patient it helps to protect the rest of the household from infection. Atcham is mentioned as a new synthetic compound, and the implication is that it has the same action as plasmochin.

The section on skin diseases deserves special mention; this chapter is illustrated freely. None of the illustrations (in this section) are in colour, but they seem to lose nothing by this as the photographs have been carefully selected and are very well reproduced.

This is not only an excellent textbook for students but the best reference book on *pediatrics* for the use of the practitioner that we know. This edition has surpassed the very high standard set by its predecessors.

L. E. N.

INTERNAL MEDICINE: ITS THEORY AND PRACTICE IN CONTRIBUTIONS BY AMERICAN AUTHORS.—Edited by John H. Musser, B.S., M.D., F.A.C.P. Second Edition. 1935. Henry Kimpton, London. Pp. xix plus 1288. Illustrated. Price, 45s.

This is a textbook of medicine arranged on traditional lines. The title is peculiarly American, and as the writers are all teachers in universities in the United States the American point of view is given preference, but not to the entire exclusion of all others, so that the reader with national prejudices need not be suspicious. There are twenty-six contributors and each is a master of the subject on which he writes. The days of the giants having passed with Osler, this form of textbook is the only one that will be tolerated in the future, but its success will depend as much on its editor as did that of the textbook of the past on its author; the editor in this instance appears to us to have been particularly successful in welding the contributions into an homogeneous whole, and in circumventing both repetitions and contradictions.

It is hard to discuss the individual contributions in a book of this kind. One's criticisms tend to be mostly with reference to omissions, and, in a book of twelve hundred and fifty pages that covers the whole subject of medicine, omissions must be condoned. One paragraph that struck the reviewer as disappointing was that on the specific treatment of lung tuberculosis; B. C. G. vaccine was the only 'specific' mentioned, but surely this vaccine has sprung into fame far more as a preventive measure than as a form of treatment?

The subject of tropical diseases is treated far more efficiently than is usual in a book on general medicine. Malaria and dysentery are given as much space as many of the important diseases of temperate climates, and in these sections all the recent advances are incorporated. (For chronic amebiasis viiform is recommended but carbarsone is referred to and is reported as giving good results.) It is all the more surprising therefore that for the treatment of kala-azar sodium antimony tartrate is given as the standard treatment and the dosage with this drug is described in detail, whereas neostibosan (wrongly called stibosan) and urea stibamine are only referred to as being said to give better results. Similarly, for the

treatment of oriental sore the antimony compounds are advocated and berberine sulphate is just mentioned.

The book is written in good English with only a few of the American spellings and constructions that are liable to distress those who have any feelings on the subject of the purity of our language. It is a book that we can recommend to the student and as a book of reference to the practitioner.

L. E. N.

AMEBIASIS AND AMEBIC DYSENTERY.—By C. F. Craig, M.D., M.A. (Hon. Yato), F.A.C.P., F.A.C.S., Colonel, United States Army, retired, D.S.M. 1934. Baillière, Tindall and Cox, London. Pp. viii plus 315. Illustrated 54 figures. Price, 22s. 6d.

This book is obviously written mainly for American circulation for even the title is spelt according to American ideas (there appear to be no rules governing the American mutilation of English). The words 'Amebiasis' and 'Amebic' appear to have no justification whatever for the author accepts the spelling of the causative organism as ending in 'ameba'. Such inconsistency shows up this type of Americanism in its true light, it is straining to produce a characteristic American atmosphere in a language Americans have accepted as their own and it has neither the recommendation of increasing simplicity nor of consistency.

The specific name *Entamoeba histolytica* is used throughout, thus classifying the parasite generically with *Entamoeba blattæ* Leidy, 1879. This is also an American fad, not accepted anywhere else in the world, and like the spelling habits calculated to confuse rather than clarify the subject. An explanatory note of this difference of opinion should have been given for the benefit of readers not versed in the niceties of zoological nomenclature.

The book as a whole is well written and gives a good account of *Entamoeba histolytica* infection in all its aspects, but there is a preponderance of references to American work as opposed to that of authorities in other parts of the world. This is especially noticeable in the section on geographical distribution, for the records of the United States occupy three pages and a table, whereas the rest of the world is dismissed in one page and a table, and some countries from which records are available are not even named.

For many years the author of this book has devoted much time and energy to the subject of the importance of amebic infection without any previous or present history of dysentery, and his chapter six dealing with this aspect of the matter is particularly valuable and should be carefully read especially by practitioners in temperate climates rather than in the tropics, for the latter are usually well aware of the importance of this form of amebic infection, whereas the former rarely suspect its presence.

The chapters on pathology are also especially good and many of the illustrations in this section are very fine, unfortunately the same cannot be said of some of the high power photographs of amebæ, for example, figures 7 and 45 which claim to show nuclear structure would need a vivid imagination to enable one to see what they are said to portray.

Treatment is fully discussed and is quite up to date, all the more recent methods being given, but here we note the only records quoted for the use of carbarsone are those of Anderson and Reed whereas reports of the successful use of this drug in a considerable number of cases in Calcutta have been published in this journal.

A few errors in printing are noted but most of them are obvious and lead to no doubt as to the meaning implied, except in the case of figure 33 where it is not quite clear what is meant by the '.....later chest wall'.

On the whole it is a useful production and is a valuable summary of the principal work on amebic

dysentery. On account of the preponderance of references to American work, already referred to, this book will be principally read in America, but it will be of great use to practitioners and research workers in other countries as well, and we feel that a much wider circulation would be assured if a fairer balance were struck between the work in the United States and the rest of the world.

P. A. M.

ABSCESS OF THE BRAIN: ITS PATHOLOGY, DIAGNOSIS AND TREATMENT.—By E. M. Atkinson, M.B., B.S. (Lond.), F.R.C.S. (Eng.). 1934. Medical Publications Limited, London. Pp. x plus 289, with 45 illustrations. Price, 21s.

This book is the Jackson Prize essay of 1926 rewritten, enlarged and brought up to date. It is divided into five sections.

Section I deals in detail with the pathology of brain abscess and is full and very lucid.

Section II, the longest of the book and the most important, describes the diagnosis. The customary method of dividing the progress of the condition into four stages, the invasive, the latent, the compressive and the terminal, is followed.

Section III deals in detail with treatment under ten headings.

Section IV gives a detailed description of twenty-eight personal cases.

Section V is composed of four sections, statistical tables, bibliography, index of proper names and a general index.

The book is primarily written for the aural surgeon but there is much in it which will repay study by general neurological surgeons. The author stresses the early general signs because those given in textbooks as the general signs of a brain abscess, headache, vomiting and slow pulse, are really ones which appear much later in the disease when compression is beginning.

He again stresses the importance of diagnostic puncture of the brain which opinion is at variance with the usual teaching. He compares diagnostic puncture of the brain by the otologist to exploratory laparotomy by the general surgeon.

The section on localizing signs of intracranial suppuration is especially good. The author does not favour any method of dealing with the abscess other than washing out the cavity gently with saline, using two tubes which are left in and shortened from time to time.

The whole book is well written and the illustrations are clear and informative, and it will for many years be the standard work of the subject in the English language.

F. J. A.

VITAL CARDIOLOGY: A NEW OUTLOOK ON THE PREVENTION OF HEART FAILURE.—By Bruce Williamson, M.D. (Edin.), M.R.C.P. (Lond.). 1934. E. and S. Livingstone, Edinburgh. Pp. viii plus 344. Available from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 11-4

This book presents the problems of cardiology in a new and most instructive light. The views put forward are the outcome of minute clinical observation and clear reasoning. The author is advocating the earlier treatment of cardiac dysfunction by conservative methods and emphasizes the importance of economy in regard to the reserve power of the heart.

New views are expressed with regard to the treatment by prolonged rest of rheumatic lesions and it is suggested that prolonged immobilization is a potent factor in the production of mitral stenosis. Though this is a little difficult to accept, we must readily agree to the point frequently disregarded, that the young heart requires exercise for its development, not by insisting on unnecessary immobilization

we may prevent the heart from developing a reserve power which will be so necessary later in life to a heart handicapped by valvular lesions.

The author is to be congratulated on the manner in which he has presented the subject and on the way in which the reader's attention is attracted from the first to the last page. We are fully convinced that any student or practitioner who reads this book will have not only his understanding but his interest in the problems of cardiology very materially increased.

E. H. V. H.

THE MEDICAL AND ORTHOPÆDIC MANAGEMENT OF CHRONIC ARTHRITIS.—By Ralph Pemberton, M.S., M.D., F.A.C.P., and Robert B. Osgood, A.B., M.D., F.A.C.S. 1934. Henry Kimpton, London. Pp. vii plus 403. Illustrated. Price, 21s.

This book is the outcome of the collaboration of a physician and an orthopædic surgeon.

The literature on the subject of arthritis under various names is overwhelming and, to anyone interested in the subject, the study has been time consuming. This volume presents the subject in a comprehensive manner.

The authors lay great stress upon the generalized nature of the disease of which the joint condition is but one manifestation. It is for this reason that they write so strongly concerning the extravagant claims for various drugs and procedures which are offered to the profession.

The writers state that their chapter on the treatment with vaccines 'will achieve little popularity'. They feel that vaccine therapy 'has received over-emphasis'. All medical men who have treated these cases with vaccines will agree with this.

There is no doubt that a definite advance has taken place in the treatment of chronic arthritis, but it is only by applying the various methods of treatment given in this volume that such results are brought about.

In the preface a note of hope is struck when the authors state that chronic arthritis is largely a preventable and curable disease. Orthopædic co-operation should not be necessary but as treatment is at present, such co-operation is inevitable. Physicians who have to treat cases of chronic arthritis should study this book. A more widespread knowledge of the underlying principles would do much to dispel the pessimism in the profession and even more amongst the general public.

The book is well written and is printed in bold type. The illustrations especially on appliances and surgery are clear and informative. The bibliography is extensive there being one at the end of most chapters together with a separate index of authors at the end of the book.

F. J.-A.

SUMMARY OF THE TREATMENT OF FRACTURES AND DISLOCATIONS.—By R. Broomhead, M.B. (Leeds), F.R.C.S. Jowett and Sowry Ltd., Atblon Street, Leeds, 1. Pp. 39. Price 3s. 6d. Including postage. Also obtainable from Henry Walker (Bookseller), Limited, Briggate, Leeds, Yorks.

The present brochure has been carefully compiled in a tabulated form, containing a summary of the causes and treatment of common fractures and dislocations, in accordance with the usage and practice of the orthopædic department of the General Infirmary at Leeds. It is mainly intended for the benefit of the medical students of the Infirmary as a refresher and guide to treatment. Charts and tables are apt to defeat their own purpose, because they tend to encourage cramming. Used intelligently along with clinical work this booklet would be found useful in many ways. Others, however, will gain some idea about the excellent routine work that is being done in a large hospital like the General Infirmary at Leeds.

P. N. R

THE ANATOMY OF SURGICAL APPROACHES.—By L. C. Kellog, A.B., M.D. 1934. Pp. x plus 134. Figures 29. Price, 7s.

This is a short book of 134 pages. It is neither a book of operative surgery for the student as it is incomplete nor is it an operative guide to the surgeon, except for one or two operative procedures, such as the exposure of long bones. The book can be recommended to students appearing for their 'final', as a means of rapid revision of operative surgery. Some of the line drawings could be dispensed with as they are far from clear.

F. J. A.

INJURIES AND THEIR TREATMENT.—By W. Eldon Tucker, M.A., B.Ch. (Cantab.), F.R.C.S. (Eng.). 1935. H. K. Lewis and Co., Ltd., London. Pp. xi plus 173, with 80 illustrations. Price, 9s.

THE title of Mr. Tucker's book may give rise to some misconception regarding its subject-matter, but this will be rapidly dispelled on closer acquaintance. The scope of this book embraces the pathology and treatment of soft-structure injuries, which, as we are all aware, might give rise to a great deal of pain and disability. The author has given cogent reasons as to why absolute rest is wrong in the treatment of most injuries to joints and muscles, and why every endeavour must be made to disperse the excess of traumatic effusion. Among the numerous rational advances in the treatment of these conditions, physio-therapy and manipulative surgery naturally occupy a premier position. One of the most effective methods consists of the non-padded plaster cast of Böhler, aided by active movements. Alternatively, the anodal galvanic current of Heald and the graduated muscular contractions of Sir Morton Smart are recommended by the author with a convincing record of cases. Excessive effusion is better aspirated with all aseptic precautions.

Against the author's advocacy for the use of faradic contractions early in the treatment of injuries, the criticism might be offered that the muscles continue to waste in spite of such treatment. But there is no doubt that recovery is far quicker than if no faradic contractions had been given. The claims of different methods of physio-therapy have been adjudicated with impartiality and their indications clearly set forth. But, we confess, we would have liked to know something more definite about short-wave diathermy therapy and its results. Nevertheless, we have much pleasure in welcoming this admirable little volume. In some places, perhaps, it suffers from too much brevity and condensation; a little more amplification would have been appreciated. The illustrations are excellent and the various grips and manipulations have been clearly explained.

P. N. R.

ESSENTIALS OF PEDIATRICS FOR NURSES.—By Philip C. Jeans, A.B., M.D., and Winifred Rand, A.B., R.N. J. B. Lippincott Co., Philadelphia and London. Pp. xii plus 503, with 73 illustrations. Price 12s. 6d. Obtainable from Messrs. Butterworth and Co. (India), Ltd., Calcutta. Price, Rs. 9-6

THIS book is subdivided into four parts, the first deals with normal development and care in infancy and childhood; the second part deals with nursing of the sick child and its technique; infant nutrition and nutritional disorders are considered in the third part; and the last one deals with malformations and diseases. On the whole, the general plan of the book is based on sound principles, but an equal degree of precision and accuracy with regard to practical details has not been maintained throughout. For feeding with lactic acid milk, the ordinary pin-hole rubber nipple will not do; its orifice will have to be enlarged; this is easily done with a red-hot needle. In cases of severe

diarrhoea, skimmed lactic acid milk is preferable. The carbohydrate mixture is replaced with 5 per cent dextrin. The omission of rice water, which has secured a recognized place in infant dietary, is also regrettable.

The management of congenital herniae in infants is inadequate. A skein-of-wool truss will generally control an inguinal hernia, but it must be constantly worn. For babies a washable pneumatic truss is very serviceable. We are afraid that a strip of adhesive plaster is not suitable for the control of umbilical hernia in infants in this country, especially during the summer months. The old-fashioned 'coin and binder' has much to recommend it. It has the additional advantage that no injury is caused to the delicate skin. For the treatment of impetigo contagiosa, a 3 per cent ointment of ammoniated mercury has been prescribed, but this is very likely to give rise to a troublesome form of dermatitis. It has been our practice to use a 1 per cent ointment with gratifying results. The treatment of burns is equally unsatisfactory. There is no mention of the tannic acid method of treatment!

All these are rather serious foibles, which are bound to detract from the utility of the book. It would, therefore, require a careful revision for the next edition to make it more practical and up to date. The printing, get-up and illustrations are beyond reproach. A glossary and an index have also been appended.

P. N. R.

THE INFLUENCE OF HEREDITY ON DISEASE.—By L. S. Penrose, M.A., M.D. 1934. H. K. Lewis and Company, Limited, London. Pp. vii plus 78. Illustrated. Price, 5s.

THE author has amplified his Buckston Brown Prize essay and published it in the form of a book. It was not the author's purpose to write a treatise on the subject and therefore he has had to exercise selection in the heredity problems that he discusses.

The importance of genetics in medicine is likely to increase rather than to decline in the near future, though the time has not yet come, and probably never will come, when the application of genetic principles can replace entirely the methods of controlling disease that are applied to-day, our knowledge of genetics has reached a stage where certain general principles can be laid down for the guidance of the physician and as a foundation for genetic research in the future.

In this essay Dr. Penrose explains in language that the physician, without a special knowledge of mathematics, can understand on what these principles are based and concludes with a very concise but valuable summary.

It is a book that we can recommend to those who are interested in the subject of genetics, and also to those who are not yet but feel that they ought to be; the latter will find it a very suitable introduction to the subject.

MEDICAL RESEARCH COUNCIL. The Inheritance of Resistance to Bacterial Infection in Animal Species: A Review of the Published Experimental Data.—By A. Bradford Hill. (Special Report Series, No. 196.) 1934. Published by His Majesty's Stationery Office, London. Pp. 71. Price, 1s. 3d.

THE measurement of the relative importance of environmental and inherited factors in the production of differences in immunity to bacterial infection is by no means an easy task. Especially difficult is it to assess the influence on the average resistance of a herd, or a community, of the selection of genetically more resistant animals as compared with immunization by non-fatal infection. From the genetic standpoint the comparison of persons exposed, apparently, to similar risks of infection is complicated by possible undetermined differences in environmental factors,

such as personal habits and personal hygiene. Equally important is the frequent lack of knowledge as to whether or not the individual has had previous contact with the infection in question. It is obvious that often the same uncontrolled or unknown factors may disturb racial comparisons amongst human beings and throw doubt upon reported genetic differences. It is difficult to determine whether an inherited rather than an acquired immunity is involved, or the extent to which both are playing a part. On the other hand, it is quite clear that constant and true-breeding differences in resistance to particular diseases distinguish various species'.

The published experimental evidence on this subject is reviewed and summarized in this monograph.

MEDICAL RESEARCH COUNCIL. Medical Uses of Radium: Summary of Reports from Research Centres for 1933. (Special Report Series, No. 197.) 1934. Published by His Majesty's Stationery Office, London. Pp. 40. Price, 9d.

This report summarizes the results of research work in the treatment of cancer—and also of some non-malignant conditions—which has been done during 1933 by means of radium lent by the Medical Research Council to selected centres throughout the country. It continues the accounts given in the eleven similar reports which have preceded it.

In addition to describing work done during the past year the report gives statistical data relating to the after-histories of patients treated in earlier years. It contains, further, a section dealing with some purely experimental inquiries into the action of radium'.

THE STATUS OF ENZYMES AND HORMONES IN THERAPY.—By G. F. Walker, M.D., M.R.C.P. (Lond.). 1935. John Wright and Sons Limited, Bristol. Pp. 48. Price, 2s.

The author's opening words are 'I suppose no one will deny that a great deal of confusion—to use no harsher word—exists in therapy with endocrine and similar products'. The harsher words that the author refrained from using were presumably 'quackery and commercial exploitation'. If this is what he meant we quite agree with him, and we think that his little book should prove a very valuable corrective.

He who sets out to use glandular preparations, says the author, should ask himself the following questions:—

1. Do I clearly recognize in my patient a hormonal lack?
2. Do I hold in my hand the truly appropriate remedy for that lack?
3. Is the preparation stable, active, pure, and uniform?
4. Can I accurately determine the dosage?
5. Is the preparation smoothly active when administered by the route I propose?
6. Are ill-effects impossible?

Even if these questions cannot be answered in the affirmative, he gives the prescriber one more chance, provided the preparation he proposes to use is harmless; he must ask himself 'Is the therapy really justified as a simple clinical experiment or under the authority of empiricism?' If he cannot give himself an unequivocal answer to this question, then he must not proceed with the treatment on the lines he was proposing.

We are afraid that the last question will let out too many practitioners with elastic consciences, as few realize the responsibilities that a simple clinical experiment entails for the experimenter.

The author has then taken each glandular preparation in the *British Pharmacopæia* and the *British Pharmacopæia Codex* and discussed very concisely what can and what cannot be expected from their use.

A book can be read in about an hour. It is a good thing for the medical profession of

this country—or of any other—if every member were compelled to read it from cover to cover. And though it can be read in an hour it is a book that is well worth adding to the small row of reference books that the practitioner keeps on his table.

MEDICAL RESEARCH COUNCIL. Tests for Respiratory Efficiency.—By Alan Moncrieff. (Special Report Series, No. 198.) 1934. Published by His Majesty's Stationery Office, London. Pp. 62. Price, 1s.

'MODERN diagnosis and treatment make an increasing demand for methods by which the functional efficiency of organs or systems of the body may be objectively and quantitatively determined. It is important alike for the physician and for the surgeon to be able to assess the degree of impairment with which he has to deal. It may also be necessary to have means of measuring a disability for such purposes as those of compensation claims. Apart from ill-health, moreover, there may be occasion for efficiency tests in the selection of individuals for occupations which make more than the ordinary demands upon a given function.

In the case of the respiratory system, the search for a satisfactory method of estimating efficiency has already a long history, and has followed various directions: it has nevertheless not yet been wholly successful. The object of the work which Dr. Alan Moncrieff undertook, with the aid of a grant from the Medical Research Council, was accordingly to investigate the value of the different methods that are available, and the possibilities of improving them. The conclusion reached is that no one test can be relied upon, and that a patient's "vital capacity", ventilating efficiency and expiratory force must all be reviewed to gain a useful estimate of respiratory function. Dr. Moncrieff has described a technique which not only gives the necessary information on these points, but which can be rapidly carried through with a minimum of discomfort to the patient. This method will no doubt be useful in the clinical evaluation of respiratory efficiency in both medical and surgical cases. The report should also be of great assistance as a detailed presentation of the known facts of this important problem, and should stimulate further investigation'.

THE INTERACTION OF THE LYMPH AND BLOOD GLANDS.—By D. Montgomery Paton, L.R.C.P. et S. Edin., etc. 1935. Baillière, Tindall and Cox, London. Pp. xi plus 173, with 80 illustrations. Price, 9s.

In the Year of Grace 1889, Dr. D. Montgomery Paton, armed with an L.R.C.P. et S. Edin., etc., went forth into the world to practise medicine. In the first nine years he practised his profession on orthodox lines—this much we are told—and we hope that his patients played the game and reacted in the orthodox manner to his treatment. Then it began to dawn on Dr. Paton that there was more in medicine than the textbooks had told him. He found that patients sometimes got better, even if you treated them for the wrong disease, and even if you gave them a form of treatment that should not, according to the textbooks, cure any disease at all. He found himself at the parting of the ways; was he to disbelieve the textbooks or was he to disbelieve his own eyes? He chose the way that Harvey would have chosen, he snapped his fingers in the face of orthodoxy, and for thirty years or more he followed the dictates of his own experience!

If the cases that the author quotes in his book are fair samples of his patients he must have been a very successful, or a very lucky (which comes to much the same thing), practitioner. His essays at experimental medicine were less fortunate. Animals would die when they should have lived, or would live when they should have died. Rationalization came to his rescue and a codicil was added to his theory, so that it all

came right in the end. However, he said, why bother about experiments on animals when the human race is before one, clamouring to be experimented upon, and so he turned away impatiently from these stupid little animals, and returned once more to the practice of medicine on *Homo sapiens*.

Dr. Paton has now retired and has had time to ruminate on his past. He has evolved a theory to fit his experience, and has, we believe, presented it

in this book; it isn't a very convincing theory, nor has he expressed it very clearly, but there it is for anyone who wants to hear about it.

Dr. Paton's major 'discoveries' include the oral administration of anti-diphtheritic serum for streptococcal and staphylococcal infections of all kinds, and emetine for alcoholism, neurasthenia and other disorders of the nervous system.

We cannot recommend this book to anybody.

Abstracts from Reports

ANNUAL REPORT ON THE WORKING OF THE RANCHI INDIAN MENTAL HOSPITAL, KANKE, IN BIHAR AND ORISSA, FOR THE YEAR 1933. BY J. E. DHUNJIBHOY, MAJOR, I.M.S., SUPERINTENDENT

THE accommodation of the hospital remained the same as in the previous years, viz, 1,014 for males and 272 for females, total 1,286. The 50 extra emergency beds sanctioned by Government in 1929 to relieve congestion in the male section were in demand throughout the year. The daily average strength of the male patients during the year was 1047.12. Many improvement and expansion projects could not be taken up owing to financial reasons. There was no overcrowding in the female section.

A considerable number of the new admissions were not really new in the true sense of that expression, but were cases of long-standing mental disorder who, in default of proper mental hospital accommodation and for other reasons, had been detained for shorter or longer periods in jails or at home. Taking into consideration the above state of affairs, the figure 27.78, showing the ratio per cent of cases cured to the so-called total new admissions in the year 1933, can be rightly looked upon as extremely satisfactory and serves as a direct incitement to the staff who devote every possible care to the employment of the modern methods of treatment to the newly-admitted patients in the reception wards of this modern mental hospital.

As in the previous years, malaria has been responsible for a large number of cases of sickness during the year under review. All practicable measures were adopted to prevent the breeding of mosquitoes inside as well as outside the hospital area by the sanitary squads of the hospital under the direct supervision of the second assistant superintendent and myself. In spite of all stringent sanitary measures to prevent the breeding of mosquitoes, no satisfactory results were achieved on account of the vastness of the breeding grounds (paddy-fields) in the immediate vicinity of the hospital which always remained a source of danger. Moreover, a small area within the male enclosure also proved a great menace to the health of the patients of the blocks situated in close proximity to this insanitary area. On account of the deficient drainage in this area, the water stagnates and it helps the breeding of mosquitoes. The managing committee have recommended to Government to rectify this and have passed a scheme costing Rs. 1,180 to provide adequate drainage in this area. Statistics show that nearly 50 per cent of the positive malaria cases of the year under review were contributed by this insanitary area in the male enclosure.

Paying patients.—During the year 91 patients (62 males and 29 females) were treated as compared with 83 (17 males and 26 females) in 1932 and 86 (61 males and 25 females) in 1931. The popularity of the hospital with this class of patient is fast growing and every year we are obliged to refuse admission to several paying patients for want of accommodation. The scheme of building separate wards for paying

patients could not be considered owing to continued financial stringency.

As sulphur therapy proved very satisfactory in previous years this treatment was continued during the year under report.

I have been experimenting with sulphur injection since 1930 and up to the end of 1933 I have treated 215 cases suffering from various mental disorders with very satisfactory results. Out of 211 cases 81 remained stationary, 85 improved in their mental health and 35 completely recovered. It is very gratifying to record that since our publication of the good results of our pioneer work with sulphur injections in India many private practitioners have adopted this treatment with encouraging results. One of the practitioners, Dr. K. K. Sen, published an article on the success achieved by sulphur injections in one of his cases which appeared in the *Indian Medical Gazette* of September 1933.

Occupational therapy.—Reference has frequently been made in our annual reports to the value of occupation and particularly all outdoor occupations in the treatment of the insane. While employment out of doors is recognized as being of the greatest value, there are many patients who cannot or will not take part in work of the hospital garden or even in domestic occupations and for them provision has been made by the establishment of occupational classes where instructions in various arts and crafts are given by experienced instructors. The variety of occupations provided is such that there are few patients for whom some congenial form of occupation cannot be found, and the good results both in the contented mind and the consequent improved bodily condition of the patients as well as the high quality of the articles produced give a return entirely out of proportion to the small initial and recurring cost. It is a mistake to suppose that occupational therapy is impossible without the employment of a few costly and highly trained occupational therapists. During the year under review a great effort was made to engage patients who were normally regarded as turbulent or unemployable with a view to making them happier and more tractable. This experiment has shown that practically every ambulant patient can be employed and is infinitely better and more easily controlled when he is employed. The medical officers in charge of such turbulent patients report that these patients are now sleeping well at night which they never did before without hypnotics, have good appetites, eat well and look much fitter and better than before and have put on weight. A very brief outline of work done is as follows:—

Weaving, cane and bamboo work, smithy, carpentry, tailoring, cobbling, mending cloths, mattress and pillow making, lace making, knitting, embroidery work, durrie making, gardening, joss stick making and miscellaneous and domestic work.

Garden work.—The vegetable garden of this hospital is one of the best of its kind in the provinces of Bengal and Bihar and Orissa. It is run entirely with patients' labour and the average number of patients

employed in the garden throughout the period under report was 200.

A variety of good vegetables, fruits, fodder, etc., were grown in the hospital garden and the produce was more than ample to meet the annual requirements of the institution.

Reward to good workers.—Besides the daily extra gifts of cigarettes, tobacco and other comforts of life, a sum of Rs. 600 is annually divided amongst hard-working patients. They look forward to this reward and spend it as they like and some of them even send this money to their families.

Sports and amusements.—These continued, as usual, throughout the year, and have proved to be of excellent therapeutic value.

About 200 patients attend the amusement hall of both sections every evening and they enjoy various indoor games and music. The cinema which was purchased and installed during the year under report has maintained its popularity with the patients and forty-seven performances were witnessed by crowded houses with happy faces. Besides the daily usual amusements and weekly cinema shows, thirteen special entertainments were also given.

Fourteen football and 10 hockey matches were played with outside teams. The annual sports, a great event to which patients look forward, was held as usual and several prizes were distributed to the winners of different events.

The hospital band played at all the entertainments and continued to be a source of great enjoyment to the patients. The band party consists of 12 attendants of the hospital and is conducted by Naik Shibcharan through whose efforts it has maintained its efficiency and progress.

Picnics.—These are a notable feature of amusement for the patients and are greatly appreciated by them.

Dietary.—The dietary of this hospital is good and varied and the cost is remarkably low. The feeding of all patients is strictly supervised by the medical officers. Weights of all patients are recorded every month and the charts maintained indicate a general rise of weight. Patients found to lose weight steadily are at once segregated in the infirmary for adequate treatment. Extra nourishing diets are given to weak and anæmic patients.

There is much more matter of interest in this report but what we have given shows that the patients are well cared for.

REPORT OF THE DIRECTOR OF THE SCHOOL OF TROPICAL MEDICINE OF THE UNIVERSITY OF PUERTO RICO FOR THE YEAR ENDING JUNE 1934

Department of Bacteriology

THE activities of the department of bacteriology have, for the most part, been devoted to the study of tuberculosis, and recurrent lymphangitis.

One of the important findings of this department this year has been the development of a skin test for *Brucella* infection. This achievement may be of immense practical significance and of considerable economic value. Besides the development of this diagnostic method, attempts have been made to fractionate the organism into its different chemical constituents. Considerable advance has been made during the year in the study of the streptococcus problem in Puerto Rico. So far, thirty strains of hemolytic streptococci have been isolated and carefully studied and compared with the streptococcal strains from the United States. To date, no difference has been established between the northern and southern strains. The immunological response of lymphangitis cases to hemolytic streptococci and their products is being studied; also the allergic reactions in these same cases have been carried out by testing intradermally with filtrates of Beta-hemolytic streptococci.

Department of Clinical Medicine

The various phases of the clinical aspects of schistosomiasis have been studied. Through the joint efforts of the hospital staff and the department of bacteriology, extensive work has been in progress on filariasis and lymphangitis, sprue, pernicious anæmia and uncinariasis, diseases of the skin and their ætiological agents.

Department of Parasitology

The members of this department, either alone or jointly with other departments of the school and hospital, have engaged in several quests of scientific interests and of practical importance. Together with Dr. E. C. Faust of the Medical School of Tulane University, they have made interesting progress on the historical, epidemiological, biological, pathological, clinical and preventive aspects of schistosomiasis *mansoni* in Puerto Rico. This study of schistosomiasis has been divided into seven main divisions, each aspect of the problem being handled by the personnel of the different departments. It seems only appropriate to mention that the data, thus obtained, have been highly significant, and will furnish an important clue for the pathological and clinical studies now being undertaken, and for the questions of prevention and of control.

The increased appreciation of the importance of the development in this laboratory of more specific methods of detecting ova of *Schistosoma mansoni* has led many physicians and individuals from various districts of the island to apply for diagnosis. Weight has been attached to the skin test as a more reliable method for diagnosis in preliminary trials, since in the initial stage of the disease, in long-standing chronic cases, and in others where only one sex of the worm is present, ova are non-existent, or practically non-existent, in the stool. The treatment of schistosomiasis with Fouadin has continued with considerable promise.

In addition to the above investigations, time has been given to the work of the pathogenic protozoa, *Entamoeba histolytica*, and to the liver-fluke, *Fasciola hepatica*.

During the year, human infestations by the liver-fluke have been found. Owners of infected animals have been advised regarding such parasitic invasion; in some cases treatment has been administered with beneficial results.

Studies of the blood in cases of anæmia, associated with hookworm disease and schistosomiasis, have been continued. Worm ova and helminth counts in connection with these diseases have followed as a regular routine experimental procedure. In conjunction with the department of clinical medicine, treatment for cestodes, by means of the duodenal tube, has been tried with partially favourable results. With the co-operation of the department of chemistry, determinations of iron content of the whole blood in cases of sprue, malaria and intestinal parasites have been initiated. The work on the specificity of helminthic antigen, in relation to experimental diagnosis, is completed and in press.

Department of Mycology

Three cases of chromoblastomycosis have been found on the island, which indicates that Puerto Rico can be considered as an important focus of this rare disease. A revision has been made on a previous study of pathogenic fungi, associated with epidermophytosis. Investigations that have been made on laboratory contaminants may lead to the disclosure of certain facts that may be of importance in the field of general mycology.

The work on monilia infection has continued. The immunological and serological reactions of the pathological fungi have been studied with the purpose of testing the agglutinating properties of certain strains, isolated from the stools of sprue patients.

Within the year four cases of granuloma inguinale have been found, of which the supposed causative agent and its fermentation reactions have been studied. The epidemiological aspects of this disease is receiving consideration.

REPORT ON THE ADMINISTRATION OF THE DELHI MUNICIPALITY FOR THE YEAR 1933-34. VOLUME II. ANNUAL REPORT OF THE MEDICAL OFFICER OF HEALTH FOR 1933

Population.—The mid-year population for 1933 is 353,747 plus 4,981 equal to 358,728. In my last year's report I put up a statement giving the areas and the populations of the first class cities of Upper India and pointed out that no other first class city of India is so dangerously and terribly congested as Delhi city. The number of people per acre in the city works out to 90 per acre or 57,739 per square mile. The city which stands next in congestion is Cawnpore with a population of 44 per acre or 28,343 per square mile. Lahore, the capital of the Punjab, has a population of 25 per acre or 15,387 per square mile and Lucknow the most important town of the United Provinces has a population of 24 per acre or 15,258 per square mile.

Delhi city is peculiarly situated on account of its being hemmed in on all sides by other municipalities (New Delhi, Civil Lines and Fort) and the river Jumna. The only avenue of extension therefore lies on a portion of its western border. Delhi city since the inauguration of Delhi as the capital of India has suddenly sprung into great importance and there has naturally been a large influx of people from all other places and this fact should be reckoned as a potent factor in the great increase of population and the consequent overcrowding. The task before the municipal committee regarding opening out of the congested areas, remodelling of the slums, etc., is stupendous but not insurmountable. Particular attention should be paid to prevent cropping up of new slums and fresh overcrowding.

Smallpox.—The year under review witnessed a very severe epidemic of smallpox. The total number of cases of smallpox recorded during the year under review was 3,681 with 808 deaths. A statement of smallpox cases and deaths during the last five years is given below:—

Year	Cases	Deaths
1929	162	66
1930	542	362
1931	44	17
1932	517	166
1933	3,681	808

Cholera.—Two cases of cholera were reported during the year under report. Both these cases were imported. One was imported from Hardwar and the other from Patiala.

Plague.—Plague was absent during the year under report except for one case which was imported from the district of Bijnor.

Fevers.—Four thousand and sixty-two deaths from fevers (excluding enteric fever and malarial fever) were recorded during the year under report as compared with 3,025 in the preceding year. Of these 1,902 occurred among males and 2,160 among females.

Malaria.—The year under report witnessed unprecedented heavy rains (60 inches against an annual average of 22 inches). Heavy rainfalls were also noticed in the hills and on the plains with the result that all the areas along the river Jumna were inundated. On the subsidence of the floods, innumerable pools were formed and as a sequence malaria broke out in epidemic form.

Respiratory diseases.—Two thousand three hundred and sixty-eight deaths were recorded from respiratory diseases, excluding phthisis, out of which 1,279 occurred among males and 1,089 among females, and 493 deaths

were reported from phthisis during the year under report.

Tuberculosis is still rampant in this city. Unfortunately the building by-laws are very defective. They do not ensure provision of adequate amounts of light and air in houses, particularly in the ground floor rooms. Moreover unhygienic houses are increasing in number. More than that some of the newly-created *basties* are nothing short of new shums. This city has innumerable narrow and tortuous alleys wherein ventilation is most defective. All these factors tend to keep the disease on the increase. On the one hand the city is being turned into a manufactory of tuberculosis, while on the other hand attempts are being made to put up clinics and sanatoriums to alleviate the sufferings of the unfortunate victims of this disease. The preliminary and most essential action required is to prevent creation of new 'plague-spots' in the city and to remove those that exist at present.

Cerebrospinal fever.—Scattered cases of cerebrospinal fever occurred in the different wards of the city. The first case came to notice in the month of January. In February there were 2 cases and in March 18 cases. Enquiries were made from different places, but no useful information on this subject was forthcoming. I consulted the Public Health Commissioner with the Government of India and was informed that this disease has been in existence in Lahore for over a year and that there have been several cases of cerebrospinal fever in the Borsal Institute.

Control of food, milk and water supply.—The regulations framed under the Punjab Pure Food Act of 1929 were brought into operation during the year under report. The pure food regulations lay down the standards of the various articles of food.

A small laboratory has been fitted up in the health department and milk and ghi samples are analysed. The analytical work was actually started from the month of August and 422 milk samples were examined. The work of ghi analysis was started later and 75 ghi samples were analysed. Nine persons were prosecuted for selling adulterated ghi.

In the operation of the Pure Food Act and the regulations made thereunder certain difficulties have been experienced. The procedure of taking samples will have to be revised so as to ensure proper operation of the Act. After the Pure Food Act has been worked for a period of a year or so, a report on the various defects or drawbacks noticed therein, with suggestions for their rectification, will be submitted. However the introduction of the Pure Food Act and the regulations prescribed thereunder have been a distinct step in assisting the health department in taking action against the vendors of articles of food which are injurious to health or inferior in quality.

SUMMARY OF THE REPORT ON THE SESSION OF THE OFFICE INTERNATIONAL D'HYGIENE PUBLIQUE HELD IN PARIS, 8TH OCTOBER TO 17TH OCTOBER, 1934. BY LIEUT.-COLONEL J. TAYLOR, D.S.O., M.D., D.P.H., I.M.S., DIRECTOR, CENTRAL RESEARCH INSTITUTE, KASAUJI AND DELEGATE FOR THE GOVERNMENT OF INDIA

Summary

In spite of the fact that many large problems which had occupied the attention of the office for some time had been disposed of at the May session there was still a large volume of work to be got through and the time of delegates was very fully occupied.

The following are points in which the Government of India may be specially interested.

(i) The question of uniform regulations for vaccination and anti-cholera inoculation in countries through which aircraft passes from

India The committee has taken up this subject very actively and will press for the unification of regulations and for conformity with the terms of the Convention for Aerial Navigation. It is recognized that this is a question affecting all countries and the International Commission for Aerial Navigation will support the case for unification as this matter affects air transport companies.

- (ii) Ratification of the International Sanitary Convention for Aerial Navigation. It is expected that the tenth ratification necessary to bring the convention into force will be made at an early date and participation by India will be strongly welcomed.
- (iii) Measures for the eradication of mosquitoes from aeroplanes have been shown to be necessary under certain circumstances and such measures are now in routine use. Information on effective measures is available and their application in India might be tested.
- (iv) Further reports from delegates are awaited on the subject of the use of standard treatments for syphilis under the Brussels Agreement. Attention is drawn to the work of the Expert Committee of the League of Nations on courses of treatment. The action in applying approved courses is to be considered.
- (v) Communications of great value on the cultivation of vaccine lymph on chick membrane have been received. The attention of

administrative officers is directed to the possibilities which this vaccine offers.

- (vi) The communications and discussions on terminal disinfection show the modern attitude in the matter. Doubt has been cast on the use of this procedure as a routine. Experimental evidence suggests that in many cases it is of little value. It may be applicable in some cases when specific methods are applied and disinfection during the progress of certain diseases is advisable.
- (vii) The representations from India on the subject of certain Soviet ships with pilgrims passing Kameian has resulted in the U. S. S. R. Government taking action against the masters of the ships.
- (viii) On the subject of the training of medical subordinates, in which both the office and the Health Committee of the League of Nations are interested, information may be required as to the experience and practice in India. This subject will come up at the second conference at the Cape to which it is presumed India will be asked to send a delegate.

The association of laboratory workers in England with our research work on cholera in India which has developed out of the work of the office would appear likely to be of great value, and India is looked to for advance on this subject.

A very valuable series of communications were presented during the session which will be of interest to workers on the special subjects dealt with.

Correspondence

A PLEA FOR THE USE OF CONCENTRATED SALINE IN CHOLERA

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—Sir Leonard Rogers has proved beyond doubt the efficacy of hypertonic saline in the treatment of cholera. He further clearly showed that hypotonic and even normal saline has not only been found less useful but, in some cases, actually harmful.

The above facts naturally set one thinking, as to what proportion of utility is to be assigned to the two chief constituents—salt and water—of Roger's hypertonic saline.

Is the collapse in cholera due more to the loss of salts or to the fluids from the blood?

Sir Leonard Rogers has again shown that in cholera the salts are excreted proportionately much more than the fluids, resulting in the hypotonic condition of the blood, with sometimes as low as 0.6 per cent in bad cases. He further showed that, in cases where the percentage of salts in the blood could be brought up to 1 per cent or more, death rarely took place in the collapse stage.

Is it, therefore, probable that the collapse in cholera is due to the hypotonic condition of the blood, producing a vasomotor paralysis, with ultimate failure of circulation?

What happens in most cases of cholera may probably be summarized as follows—The diarrhoea and vomiting deplete the body of fluid and salts—proportionately more of the latter (the cause for this proportionately greater loss is perhaps a protective response on the part of the body to the stimulus of the cholera toxin, for, the salts and the cholera toxin form a crystallo-colloidal union, which is an essential factor in the excretion of the poison). It is, therefore, essential that this extra loss of salts from the circulation be made good, as early as possible to facilitate the excretion of the cholera toxin. This depletion

goes on until the circulation becomes incapable of supplying the splanchnic area. Then the motions and vomiting gradually get less and less and ultimately stop, so also does the urine. The splanchnic area thus becomes a closed pool as it were, with gradually increasing amounts of cholera toxin, with no hope of excretion. Thus, a vicious circle is established, a failing circulation with increasing toxins in the splanchnic pool and no excretion of toxins, this ultimately results in the complete failure of circulation and death.

Can salts alone (saline in a concentrated form—20 ccm of a 20 per cent solution) revive this failing circulation of cholera?

Perhaps they can. After reading an article by C. MERRIS (*Bull. Soc. Path. Exot.*, XXVI, 900) I had the opportunity of trying this simple method on two collapsed cases of cholera, both with cramps, suppression of urine and a failing pulse. Two more collapsing cases of cholera were similarly treated in this month at the Veduanyam festival (South India), with success; in three of the four cases, *Vibrio cholerae* was isolated. In all the four cases, the patients passed urine a few minutes after the injection of the concentrated saline with very quick relief of the other symptoms as well. All recovered without any further hypertonic saline. It is, therefore, quite possible that salt is the chief factor in reviving the circulation, and if this is supplied, even without any extra amount of fluid intravenously, the collapse of cholera will be overcome.

The passing of urine in these cases, a few minutes after an injection of only 20 ccm. of fluid, clearly shows that the revival of the circulation, even that of the kidney, is due to the salt and not to the fluid.

No definite conclusions can, however, be drawn from these few cases, but, this is certainly an incentive for further work. Even if this method, after a complete trial, were to be found less efficient than the hypertonic saline, it is bound to be the best first aid,

in the hands of the rural practitioner and the field worker whose helplessness (partly for want of equipment and partly due to inexperience of Roger's technique, simple as it is) in treating collapsed cases of cholera is so well known

Advantages

The advantages of this method are —

Simplicity—the sterile concentrated saline can be easily stocked in 20 ccm. ampoules and very easily used without any risk of sepsis.

There is no fear at all of oedema of the lungs resulting from excess of fluid.

The reaction is less likely to occur.

The copious evacuations with a recurrence of collapse that sometimes follow large injections (3 pints) of fluid are not likely to occur at all in this method.

With increasing viscosity of the blood, there is less and less likelihood of the fluid and the salts in it draining out of the circulation—(analogy of the usefulness of gum saline in surgical shock). Thus, if the salt content of the blood is kept above normal, and if the circulation is maintained thereby, without any further injection of fluid, there is less likelihood of the salt draining out of the circulation. On the other hand, when the lost fluid is replaced in the circulation, the salt is bound to be drained out at a much higher rate than if the fluid were not replaced. Thus, in the concentrated saline method, because the salt is better retained in the circulation, there is less likelihood of the necessity of more injections than one.

With revival of circulation, the kidney begins to work, but the strain on the organ is much less in this method, as there is not much fluid to be excreted. The necessity of relieving the strain on the kidney is essential in cholera where the skin is practically inactive. Thus, uræmia and similar complications may be lessened, if not avoided.

Yours, etc.,

Y. S. NARAYANA RAO, M.R., B.S., D.T.M.

KING INSTITUTE,
GUINDY,

A SIMPLE METHOD OF BUG DESTRUCTION

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I have read with interest the article on 'A simple method of bug destruction' by J. N. Pacheco in the February issue of the *Indian Medical Gazette*.

The author writes 'Coconut oil is a poison to the bed-bug'.

Grains are infected with many kinds of virus and to prevent this infection people in Gujarat use castor oil. Castor oil is heated and then rubbed in small quantities. This preserves the grains for more than one year.

Rice is similarly preserved and also small pieces of coconut are kept in the container along with the rice. This also preserves the rice from the varieties of insects' infection.

Epidemic dropsy is a disease conveyed by infected rice. I do not know whether the above-mentioned methods of preserving rice are used in Bengal. How far castor oil or coconut oil works as a poison to these insects is a question of research.

Yours, etc.,

RAMANIK H. DESAI, L.C.P.S. (Bom),

A SIMPLE METHOD OF BUG DESTRUCTION

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—With reference to Dr J. N. Pacheco's article in your February number, 'A simple method of bug destruction', I remember the coconut oil remedy being

used in a hospital many years ago, but do not know why it was not more generally adopted in other institutions.

I desire to draw attention to the following procedure which seems to be a prophylactic against bug-breeding. Hospital cots, if painted blue, do not seem to have bugs in them, whereas other cots with other paints have abundance of these insects. This seems to be in conformity with an article I read some years ago in an English journal, that bedrooms painted blue have less mosquitoes than those of other colours.

Yours, etc.,

J. F. HENRIQUES, L.M. & S.,
F.C.P.S., B.M.S.

Superintendent, Mental Hospital.

RATNAGIRI,

14th March, 1935.

EPIDEMIOLOGY OF LEPROSY

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—In the Bombay Presidency in general, and the Kolaba district (where I am working) in particular I have observed that the incidence of leprosy among Mohammedans is very low as compared with Hindi (of the same social status), although the habits and the conditions under which both these communities live are more or less identical. I believe this fact might have been noticed by other observers and leprosy workers also. I have no means of verifying this observation from statistical records and caste summaries, but people who have got these records at their disposal might be able to throw some light on this subject, and then it would be interesting to compare the percentage of leprosy incidence amongst Mohammedans of the Bombay Presidency with that of other provinces.

Yours, etc.,

ANNAJI V. GOKHALE,
Medical Officer,
Pui Leper Asylum

INTRAMUSCULAR VERSUS INTRAVENOUS QUININE

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—Dr. Adalja's letter on the above subject published in the January issue of the *Gazette*, p. 58, I have read with interest. He appears to be a great advocate of intramuscular quinine, for he not only used quinine by this route when indicated, but also expresses the opinion that in 85 per cent of cases quinine injection therapy is indicated. One can conceive that the percentage of cases requiring parenteral exhibition of the drug will vary in individual hands, but it is, I think, infliction of avoidable inconvenience, if 85 per cent of the cases are so treated as a routine. Most of the cases do well with oral administration. When the gastro-intestinal tract is angry, or when a quick therapy is indicated, the intravenous route should be the route of choice.

Though I have had considerable experience in intravenous quinine, I can count on my fingers the intramuscular injections I have given. Apart from the usual 'tetanus-vel-necrosis-phobia' associated with intramuscular quinine, my idea to use the intravenous channel has been to avoid pain and to prevent a frontal attack when indicated.

Dr. Adalja is indeed to be congratulated on his fortunate results. But it may be remarked that the criterion of success should be not the immediate control of an attack, but of avoiding relapses, and as it is not stated how many times the same individuals

occurred in the 5,000 cases, one is not in a position to comment further on the point. Anyway the letter suggests that he treated (rather cured!) each case with one intramuscular dose—indeed a great victory for the intramuscular route.

My experience in the intravenous field tells me that some of the cases who were in the habit of receiving intramuscular quinine, and had received several courses of these elsewhere, were simply amazed to see that they were relieved once for all of their periodic fever by two or three 'proper intravenous administrations'. Though I have seen such cases where intramuscular quinine failed and intravenous succeeded, I have yet to see a case where the reverse occurred. This is in itself a great point in favour of the intravenous quinine.

It may be hard to convince Dr. Adalja of the superiority of the intravenous route for he has no failures so far with the intramuscular channel, but one can venture to suggest that if he succeeds in persuading himself to give the intravenous route a fair trial and compare his notes, he will be amply convinced. There is nothing to be afraid of in intravenous quinine; if properly administered it is quite safe, effective, and quick.

In fine, one has to agree with the editor that the intravenous route should be the route of choice and that where injection is indicated the intravenous route should be given preference.

Yours, etc.,

R. L. SONI, M.B., B.S., F.R.I.C.S.

PAUNOM (BURMA),
5th March, 1935.

[We have read our editorial note again and we cannot agree that any definite preference for the intravenous route was expressed.

We specifically condemned intramuscular injection as a routine procedure; we do not consider that the routine administration by the intravenous channel deserves any less emphatic condemnation.—Editor, I.M.G.]

CONSERVATIVE SURGERY IN MALIGNANT DISEASE

To the Editor, THE INDIAN MEDICAL GAZETTE

DEAR SIR.—The paper on 'Conservative surgery in malignant disease' by Dr. T. Howard Somervell, appearing in your March issue, opens up several avenues of partly criticism and partly controversy.

Dr. Somervell gives a sarcoma patient 'a full course of deep x-ray therapy' to the growth and its immediate neighbourhood before operation. This course consists of five minutes of 5 milliamps at a 5-inch spark gap (90,000 volts), with a filter of 1 millimetre of aluminium at 15-inch target—skin distance. This dose is given every day for 10 days. I submit that such a course neither constitutes deep x-ray therapy at all, nor is a 'full' dose in any sense of the term as applied to a malignant growth. It probably would not produce 30 per cent of an erythema dose at a depth of 10 cm.

It used to be held some years ago that sarcomas were more radio-sensitive than epithelial growths and so required less radiation, and that at a lower voltage and filtration than carcinoma. While the facts of this lower 'lethal' dose is true as regards immediate results, the passage of time has shown that doses quite as large and at as low a wave length are necessary for the treatment of sarcoma, as of carcinoma, assuming that the object of treatment is to cure the disease.

After 'radical excision' of a growth Dr. Somervell leaves one milligram of radium in a needle per 1½ cm. of nerve tissue in cases where important nerves have become adherent to the growth. What filtration is used, and what is the radium concentration in these needles? Dr. Somervell is apparently in the habit of 'locally excising' bone sarcomas, or in the case of

giant-celled tumours of scooping out the contents. Both these procedures leave room for criticism.

In the case of bone sarcoma, whether of the osteogenic, 'endosteal' or Ewing's type, recent work has shown that the growth extends, as can be shown by serial sections, much further than can be seen either in a skiagram, or by naked-eye morbid appearances. In the case of long bones the disease before it is diagnosed has in the majority of cases infiltrated almost if not the whole length of the shaft. It will be obvious that the local removal of such a tumour, with three-quarters of an inch of 'healthy' bone on each side, will be of little use.

As to giant-celled tumours—the vexed question arises, what really are these growths? If considered as neoplasms of bone they certainly are not an entity in themselves—they almost certainly belong to one end of the sarcoma scale, the slowly-growing relatively-benign end, with little if any anaplasia, at first at any rate.

The actual giant cells, polynucleate, are probably a product of slow toxæmia by the toxin of the neoplasm, just as they are in the case of tubercular 'giant cells'. If the view of Looser, that giant-celled tumours are of the nature of granulomas which sometimes undergo sarcomatous changes, is held, then treatment will obviously be influenced by the radiographic appearances. If completely encapsuled by a shell of bone, the tumour may be subjected to a local 'scooping', with canterization as described by Dr. Somervell, such scooping being done in the interval between a 30 per cent fractional series of deep x-rays followed by a complete fractional course of 1,700 to 1,800 r. units per area at 200 k.v. and a filtration either of thoræus or 1 millimetre of copper, delivered in fourteen to fifteen days. It has been shown conclusively that the majority of giant-celled tumours react well to deep x-rays and keep well after treatment.

In cases where the skiagram shows signs of malignancy, that is to say where the tumour is rapidly growing and breaking down its bony walls to invade the soft tissues, then it should be treated as if it were a sarcoma, which in point of fact it probably is. It is a moot point whether such cases should be operated upon. In frank cases of sarcoma the results of deep x-ray therapy are at least as good without the added inconvenience of parting with a limb, or part of a limb. The vast majority of patients die as a result of distant metastases, whatever one does.

In cases of abdominal new growths, where the tumour is situated in the lower abdomen we can very often obtain gratifying results by deep x-ray therapy. I have in my series a case of inoperable adeno-carcinoma of the ovary in which a piece was removed for section to establish the diagnosis in 1924. The patient had deep x-ray therapy from me and is alive and well to-day.

In the upper abdomen radiation is of less value, but even here a good deal can be done by often repeated small doses at high voltage and filtration, modifying the method of Coutard.

It is doubtful if the harmful effects noted in these cases, vomiting, collapse *et seq.*, are due to histamine shock.

I am rather puzzled by the skiagram (figure 5 in the paper), labelled 'Non-osteogenic periosteal sarcoma'. Judging by the reproduction there is no evidence of any bone sarcoma at all; what did the section show?

As regards carcinoma of the breast, the work of Keynes, FitzWilliams and others has shown conclusively that treatment of early tumours by efficient radium needling alone has in many cases eradicated the disease. It is advisable to supplement such needling by a course of deep x-ray therapy. Where a carcinoma of the breast has advanced to the size of a walnut or more, and the classical signs, nipple retraction, etc., present with or without palpable involvement of the axillary lymph nodes, then probably

the ideal treatment consists of (a) a preliminary course of deep x-ray therapy to minimize the risk of metastasis by sterilizing any wandering cells in the lymphatics in addition to an inhibitive effect on the growth, (b) operation with the endothermy knife (or needle), and (c) a complete course of deep x-ray therapy, as soon as the stitches are out, using three areas, two glancing and one superior as advocated by Finzi and Levitt, giving about 1,250 r. units to each area in a fortnight, of hard rays.

In the case of carcinoma of the uterus, the most recent figures of Heymann at Stockholm, of Regaud and Lacassagne of Paris, Murdoch of Brussels, not to mention Donaldson, Roy Ward and Durden Smith of London, all show that the radium and deep x-ray 'cures' taken on a basis of five years with no sign of recurrence are better than the best operation figures of very selected cases, not excluding those of Mr. Victor Bonney, and this without the appalling operation mortality, which in most surgeons' hands reaches the level of 40 per cent.

Professor Heymann's figures up to 1928 are as follows :—

Five-year cases in different stages of cancer of the cervix, 1914 to 1928 inclusive

	Number treated	Number of five-year cases	Cure, per cent
Stage I	.. 141	81	57.5
" II	.. 403	138	34.3
" III	.. 557	90	16.2
" IV	.. 338	18	5.3

Results have improved since 1928 and it is confidently expected that in the most recent series at the

Radiumhemmet of Stockholm the figures will be very much better even than the above.

Professor Heymann gave us an idea of these figures at the Fourth International Congress of Radiology at Zurich last summer and I seem to remember the figure being as high as 70 per cent in group I cases. This communication will no doubt be published in the Proceedings of the Congress. In any case it must be patent that, even allowing for the exceptionally gifted hands of Mr. Victor Bonney, Wertheim's operation is as dead as the Dodo.

With further advances in the technique of tele-radium treatment (the radium 'bomb') and in deep x-rays of extremely short wave length generated by plants delivering a potential of the order of a million volts, we might reasonably expect to get, and as a matter of fact are getting, nearer and nearer daily to the solution of the cancer problem.

It is not by any means my intention to disparage the very excellent work being done by Dr. Somervell at his Mission Hospital, limited, as he probably is, by want of proper deep x-ray therapy plant and an adequate supply of radium, but I wish to point out that the methods he describes are far from being the last word in the 'conservative' treatment of malignant disease.

Yours, etc.,

G. GALSTAUN, M.A., D.M.R.E. (Cantab.),
M.R.C.S., L.R.C.P. (Lond.),
Honorary Radiologist.

MEDICAL COLLEGE HOSPITALS,
CALCUTTA,
19th April, 1935.

Service Notes

APPOINTMENTS AND TRANSFERS

LIEUTENANT-COLONEL R. S. TOWNSEND, M.C., Civil Surgeon, Lucknow, is appointed to officiate as Inspector-General of Civil Hospitals, United Provinces, with effect from the 21st December, 1934, until further orders *vice* Colonel A. H. Proctor, granted leave preparatory to retirement.

Lieutenant-Colonel R. N. Chopra, C.I.E., Professor of Pharmacology, School of Tropical Medicine, Calcutta, is appointed to act as Director of the School in addition to his own duties, with effect from the 9th January, 1935, until further orders.

Lieutenant-Colonel W. P. Hogg, Residency Surgeon, Mewar, is appointed to officiate as Resident in Mewar and Political Agent, Southern Rajputana States, in addition to his own duties, with effect from the afternoon of the 12th February, 1935, and until further orders.

Lieutenant-Colonel F. A. Barker, O.B.E., is appointed to officiate as Deputy Director-General, with effect from the 22nd February, 1935, until further orders.

Lieutenant-Colonel B. H. Singh, M.C., Civil Surgeon of Burdwan, is appointed to act, until further orders, as Principal, Medical College, and Superintendent of the Medical College Hospitals, Calcutta, *vice* Lieutenant-Colonel T. C. Boyd.

Lieutenant-Colonel P. Banerji, Civil Surgeon, Chittagong, on relief, is appointed to act, until further orders, as Civil Surgeon, 24-Parganas, *vice* Lieutenant-Colonel K. S. Thakur.

The services of Major B. P. Baliga are placed at the disposal of the Government of Bengal for employment in the Jail Department, with effect from the date on which he assumes charge of his duties.

On return from leave Captain H. W. Mulligan, an officer of the Medical Research Department, is placed on foreign service under the I. R. F. A. for appointment as Assistant Director, Malaria Survey of India,

Kasauli, with effect from the date on which he assumes charge of his duties.

Major R. C. Wats, an officer of the Medical Research Department, on reversion from foreign service under the Indian Research Fund Association, is appointed as Supernumerary Officer at the Haffkine Institute, Bombay, with effect from the date on which he assumes charge of his duties.

Major A. M. V. Hesterlow is appointed to officiate as Director of Public Health for the Government of Bombay, *vice* Major A. Y. Dabholkar, M.C., proceeding on leave.

Major S. A. McSwiney, Civil Surgeon, Darjeeling, is appointed to act, until further orders, as Professor of Midwifery, Medical College, and Obstetric Physician and Surgeon, Medical College Hospitals, Calcutta, during the absence, on leave, of Lieutenant-Colonel Gow.

Major T. H. Thomas, Civil Surgeon, Dacca, on relief, is appointed, until further orders, as Civil Surgeon, Darjeeling, *vice* Major S. A. McSwiney.

The services of Captain H. H. Mahmood are placed at the disposal of the Government of the N. W. F. P. for employment in the Jail Department, with effect from the date on which he assumes charge of his duties.

Captain B. Chaudhuri is appointed to be Senior Medical Officer, Port Blair, with effect from the 19th April, 1935, or any subsequent date on which he assumes charge of his duties.

Captain R. Linton, Civil Surgeon, Bakarganj, on relief, is appointed, until further orders, as Civil Surgeon, Dacca, *vice* Major T. H. Thomas.

Captain G. B. W. Fisher, Civil Surgeon, Burdwan, on relief, is appointed to act as Civil Surgeon, Chittagong, *vice* Lieutenant-Colonel P. Banerji.

LEAVE

Colonel A. H. Proctor, D.S.O., V.H.S., Inspector-General of Civil Hospitals, United Provinces, is granted leave on average pay for three months and two days combined with leave on half average pay for a total period of eight months, with effect from the 21st December, 1934, preparatory to retirement.

Lieutenant-Colonel T. C. Boyd, Principal, Medical College, and Superintendent of the Medical College Hospitals, Calcutta, is granted leave for the period from the 14th March, 1935, or from the date of relief to the 14th October, 1935.

Lieutenant-Colonel P. F. Gow, Professor of Midwifery, Medical College, and Obstetric Physician and Surgeon, Medical College Hospitals, Calcutta, is granted leave on average pay from the 8th April, 1935, or from the date of relief to the 30th September, 1935.

Lieutenant-Colonel K. S. Thakur, Civil Surgeon, 24-Parganas, is granted leave *ex-India* for seven months, with effect from the 23rd April, 1935, or from the date of relief.

Captain V. A. Edge, Senior Medical Officer, Port Blair, is granted leave for 3 months and 16 days, with effect from the 23rd April, 1935, on the expiry of which his services are replaced at the disposal of the Army Department. Previous notification is hereby cancelled.

REMOVAL FROM SERVICE

Captain E. G. Michelson is removed from the Service, His Majesty having no further need of his services, 29th November, 1934.

Captain J. J. Quinlan is removed from the Service, His Majesty having no further need of his services, 16th January, 1935.

PROMOTION

To be Captain (on prob.)

Roland Lionel Raymond, 25th January, 1935, with seniority as Lieutenant 25th January, 1931, and as Captain 25th January, 1934.

RETIREMENT

Lieutenant-Colonel D. D. Kamat. Dated 1st March, 1935.

Notes

A COMBINED URETHRAL DILATING BOUGIE AND CATHETER

By MILROY PAUL, M.S. (Lond.), M.R.C.P. (Lond.)
F.R.C.S. (Eng.)

THIS set of bougies was made to my design by Messrs. Down Brothers, Limited, London.

The bougies have the shape of the well-known Lister's bougies and in addition each bougie has a narrow tubular channel running through its long axis, and are made in 3 sizes 4/7, 6/9, 8/11 Eng. gauge.

These bougies were designed to obviate the necessity for passing a metal catheter, in dealing with that common surgical emergency acute retention of urine from an urethral stricture.

As every surgeon knows, the passage of a bougie through a stricture is much easier than the passage of a metal catheter, even though the stricture has been first dilated by the bougie.
The slow emptying of the bladder through the

in this type of case. To the comparatively inexperienced worker, the flow of urine through the channel in the bougie is welcome confirmation of the successful passage of the bougie into the bladder.

The bougies have proved very satisfactory in practice, as they are passed more easily than a metal catheter owing to their greater weight, better balance, and their bulbous ends, and I also prefer to use them instead of a metal catheter in cases of enlarged prostate, where occasionally it is necessary to use a metal catheter to relieve acute retention.

The lesser liability to trauma of the urethral walls makes blocking of the lumen of these bougies with blood clot a rarer event than was the case with the metal catheter whose eye often blocked with soft clot, when being used in a difficult stricture case.

'HYPOLOID' CALCIUM LÆVULATE

BURROUGHS WELLCOME AND COMPANY, Snow Hill Buildings, London, E.C.1, have issued 'Hypoloid' calcium lævulate in ampoules of 1 gramme.

This product has been introduced to meet the demand for a calcium product for injection in cases where calcium therapy is indicated. It contains 14.8 per cent of calcium and is non-toxic in therapeutic doses.

'Hypoloid' calcium lævulate is indicated in the treatment of tetany, in the vomiting of intestinal obstruction, in coeliac rickets and as a pre-operative measure in various surgical operations.

It is issued in boxes of 5 'Hypoloid' ampoules.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

SOME BIOCHEMICAL OBSERVATIONS ON ASTHMA

By DHARMENDRA, M.B., B.S.

and

L. EVERARD NAPIER, M.B.C.S., L.R.C.P.

Calcutta School of Tropical Medicine

IN a previous paper (Acton and Dharmendra, 1933) it has been shown that amongst Indians bronchial asthma, *i.e.*, asthma secondary to some disease or infection of the respiratory tract, preponderates, and that asthma as a result of hypersensitiveness to pollens, animal emanations, such as horse hair, cat hair or chicken feathers, and to specific foods, such as egg and milk, is rare. Allergic asthma amongst Indians is usually dependent upon some abnormal condition in the gut, such as intestinal amebiasis or hookworm infection. But only a small percentage of the patients with chronic bronchitis or with these intestinal infections suffer from asthma; there was, therefore, some factor which differentiates the group that develops asthma from those that do not.

The biochemical investigations of Barber and Oriel pointed to a liver dysfunction existing amongst allergies; the results of liver-function tests carried out by Bray in a series of allergic children pointed to the same condition.

Acton and Dharmendra suggested that in cases of intestinal infections where the liver function is normal the toxic substances formed in and absorbed from the intestines are detoxicated in the liver, whereas, if the defence mechanism of the liver is lowered by amebic or some other form of hepatitis, the offending substances may pass through the liver unchanged, reach the general circulation and produce symptoms. In the present series of cases we have investigated certain biochemical changes amongst asthmatic patients in this country.

In addition to the examinations already detailed in the previous paper (eosinophil count, Arneth count, stool and sputum examination, skiagram of the chest, von Pirquet and dermal tests), special tests for sympathicotonia (the adrenalin test), for liver function (lævulose tolerance test, adrenalin test, van den Bergh test, determination of icterus index, examination of urine for bile, urobilin and indican), and for gastric function (fractional gastric analysis) were done in this series.

A diagnosis of the type (*vide* Acton and Dharmendra, 1933) was first made from the history and clinical symptoms of the patient, and from the blood, stool, roentgenographical, and nasal examinations and dermal tests.

In all, 42 cases were investigated. Analysis of only 40 cases will be presented in this paper;

two cases have been eliminated from the series, as one proved to be a case of right-heart failure and in the other there was active pulmonary tuberculosis in both lungs.

Amongst the 40 cases taken for analysis there are 11 in which the skiagram showed definite or suspicious signs of old apical lesions or of early infiltration of the apex. These cases have been included in the analysis because the lesions were not sufficiently advanced to be held responsible for the dyspnoea; in the cases showing early infiltration the asthma was of long standing, and the biochemical findings did not differ from those in the other cases of the series.

Of the 40 cases analysed in the paper, 27 were bronchial cases, *i.e.*, cases secondary to bronchial infection, 7 were cases of allergic asthma, while the remaining 6 were of the mixed type.

Before describing the results obtained with the biochemical tests we will very shortly describe the results of the blood and stool examination, of the radiological examination of the lungs, and of the von Pirquet test. The significance of these tests have already been considered in previous papers.

Blood eosinophilia.—The blood eosinophils were below 1,000 in 24 cases, and above 1,000 in 16 cases. The Arneth index and eosinophil count in the different types is shown in table I.

TABLE I

Type	Total number of cases	Eosinophils below 1,000 per c.mm.	Eosinophils above 1,000 per c.mm.	Arneth index above 70	Arneth index below 70
Bronchial	27	19	8	25	2
Mixed bronchial and allergic.	6	2	4	5	1
Allergic	7	3	4	2	5

Out of the 8 bronchial cases with a count of above 1,000 eosinophils per c.mm. of blood, two had the Gram-negative bacilli in their sputa.

Radiological evidence of tuberculosis.—This was found in 11 cases, 9 of which belonged to the bronchial and 2 to the mixed bronchial and allergic types. In 4 cases there were very old apical lesions, in 2 suspicious infiltration of the right upper lobe, in 4 definite early infiltration of the right or of the left upper lobe, while in 1 there was early infiltration of both the upper lobes.

The von Pirquet test.—This was done in 38 out of the 40 cases. It was positive in 22, doubtful in 3, and negative in 13 cases.

For purpose of interpreting the results of the von Pirquet test we will consider the bronchial and the mixed cases under one group, and the

allergic cases under another group. The results are summarized in table II.

TABLE II

Type	Total number of cases	Number of cases in which the von Pirquet test was done	RESULT		
			Positive	Slight positive	Negative
Bronchial, and mixed bronchial and gut cases.	33	31	21	3	7
The allergic cases	7	7	1	..	6
TOTAL ..	40	38	22	3	13

The 31 bronchial and mixed bronchial and gut cases in which the von Pirquet test was done included the 11 cases showing radiological evidence of tuberculosis; in all of these a positive von Pirquet was obtained, but in 2 it was weakly positive, whereas amongst the rest, i.e., cases in which there was no radiological evidence of tuberculosis, the test was definitely negative in 7, weakly positive in one, and positive in 12.

Blood sugar.—This was estimated in 39 out of the 40 cases. In all the cases blood from a vein at the elbow was taken from the fasting patient. The blood sugar ranged from 66 mgm. per 100 c.cm. to 100 mgm. per 100 c.cm., i.e., from 0.066 per cent to 0.100 per cent. In the majority of cases it was between 66 and 75 mgm. per 100 c.cm.; 20 cases had this value, in 12 it was between 76 and 80 mgm. per 100 c.cm. and in 7 cases it was between 81 and 100 mgm. per 100 c.cm. The mean value was 74.48 mgm. and the standard deviation from the mean ± 9.15 mgm. Table III gives the blood-sugar values of the cases of different types.

In the 33 bronchial cases the mean was 75.46 ± 10.98 and in the 6 allergic 71 ± 4.32 . The difference between these two means is not 'significant'.

TABLE III

Type of cases	Total number	Number in which blood sugar was estimated	BLOOD SUGAR VALUES, IN MG. PER C.CM.		
			66 to 75	76 to 80	81 to 100
Bronchial ..	27	27	14	7	6
Bronchial and gut ..	6	6	1	4	1
Allergic ..	7	6	5	1	..
TOTAL ..	40	39	20	12	7

In no case was the blood sugar above normal, it was normal in only seven, in 20 cases it was definitely below normal, and in 12 cases the figures were towards the low side of normal. Low blood sugar values have been found by other workers in asthma and allergy.

Payne and Bray (Bray, 1931) in a series of 55 allergic children found that 36 out of 55 showed a value below normal. Malone (*loc. cit.*) obtained low blood sugar values in a series of fifteen cases of bronchial asthma associated with suspected food allergy. Knott, Oriel and Witts (1930) at Guy's Hospital found in 62 out of 148 cases of asthma, i.e., in 42 per cent of the cases, the blood sugar below normal. Osman (1929) describes 4 cases of typical bronchial asthma in children who had been rendered entirely free from attacks by the simple addition of sugar to the diet.

Adrenalin test.—Adrenalin stimulates the sympathetic side of the autonomic nervous system. A subcutaneous injection accelerates the pulse rate and increases the systolic pressure, and there is an increase in the blood sugar from mobilization of the liver glycogen. A subcutaneous injection that normally raises the blood-sugar level has no action on the blood sugar after hepatectomy; this indicates that the blood sugar is raised by its action on the glycogen of the liver. This action of raising the blood-sugar level we will consider when discussing the liver-function tests, for the present we will refer only to the action on the pulse rate and systolic blood pressure.

Goetsch (Englebach, 1932) originally introduced the 'adrenalin test' for indicating hypersensitiveness of the autonomic nervous system. According to him, after a subcutaneous injection of 0.5 c.cm. adrenalin an increase of 20 per minute in the pulse rate and 20 mm. of systolic blood pressure indicates a positive reaction. He maintained that such a positive reaction, indicating hypersensitiveness of the autonomic nervous system, was constantly associated with hyperthyroidism. Englebach (1932) discredits the value of the test, as he obtained positive results in both endocrine and non-endocrine disorders, frequently in normal individuals, and in 3 cases in which the thyroid gland had been completely removed. From his results of the adrenalin reaction on 1,066 cases of endocrine disorders he concludes that it occurs more or less frequently in all endocrine disorders, that it occurs as frequently with the hypo-activities as with the hyper-activities of the different glands, and that the variability in this reaction was so great that no deduction could be drawn with regard to its effect upon the sensitiveness of the autonomic nervous system.

Technique.—Englebach (1932) suggests that the test be done during the morning or afternoon at least one hour after meals and at a time when the patient is free from emotion and the effects of unusual muscular exertion. In our cases, along with its effects on blood pressure, we had to test the effects of the adrenalin injection on the blood sugar also, so that all our tests were done in the morning on a fasting patient. After the patient had been in bed for some time and was physically and mentally quite calm, his pulse rate and systolic blood pressure were recorded every five minutes until constant results were obtained. Half a

cubic centimetre of a 1/1,000 solution of adrenalin hydrochloride was then injected subcutaneously. The effect of the injection on the blood pressure and pulse rate was noted. We took the readings three-quarters of an hour and again one and a half hours after the injection.

Englebach (1932) considers a variation of or within 20 mm. and 20 beats per minute below or above the recorded stationary pressure and pulse rate before the injection was given to be within the normal limits. A reduction in blood pressure of 20 mm. or more is considered a positive reaction. Similarly a decrease of 20 beats or more in the pulse rate is considered a negative reaction and an increase of 20 beats or more a positive reaction.

We did the test in 37 of the 40 cases and in all of them found the changes within normal limits. The results were also normal in the two cases not included in the analysis, one of right-heart failure with emphysema and the other of tuberculosis.

In our series the general reactions were very infrequent, and consisted only of slight tremors in a few of the cases. The general reaction may be more marked and cause tremors, twitching, pallor, nervousness, restlessness, palpitation, nausea, vomiting and sometimes a chill. Englebach does not consider the general reactions abnormal as they occur in a large percentage of normal individuals. The absence of such symptoms he considers as evidence that the patient can tolerate a larger dose of adrenalin than an average individual.

Blood pressure.—This was recorded in 37 out of the 40 cases. In all the cases the reading was taken in the morning before the patient had eaten anything. The systolic pressure ranged between 95 and 125 mm., except in the case of a child of 8 years in whom it was only 75 mm. In 3 cases it was 95, in 8 cases 100, in 3 cases 105, in 11 cases 110, in 1 case 115, in 8 cases 120, and in 2 cases 125; so that only in 11 out of 37 cases it was above 110. Of the 37 cases the ages of 22 were above 30 years (between 30 and 50 years), of 14 were between 20 and 30 years and one patient was a child of 8 years. Taking into consideration the ages of the patients all the readings were on the low side; in 26 cases they were decidedly low (75 to 110). The low blood pressure cannot be accounted for by inclusion in the analysis of the patients showing some radiological evidence of tuberculosis, as the mean of the systolic blood pressure of the whole series was 110.68 mm. Hg. whereas of those with evidence of tuberculosis it was 109.55 mm. Hg. Arranged according to ages the mean of the systolic pressures was 110.7 in the 20–30 age group, 105 in the 31–40 group, 110.8 in the 41–50 age group, and 118.3 above 50 years.

Alexander, Luten and Kountz (1927) in a series of 50 cases of bronchial asthma of all ages in whom the condition had been present at least for five years report almost universally low blood pressures.

Adam (1932) finds that in 1,500 cases of asthma only in 10.7 per cent was the blood pressure below normal, in 7.5 per cent it was above normal and the remaining cases had a normal pressure. Knott, Orie. and Witts (1930) determined the pressure in 79 cases above the age of 10 years. The values in early life were normal, and rather high after the age of 40 years.

Hypo-adrenia.—The low blood pressure and hypoglycaemia point to a deficiency of adrenalin in these patients. A connection between the onset of asthma and dysfunction of the endocrine glands, especially the adrenals, thyroid and thymus, has often been suggested.

Hurst (1930) suggested that attacks of asthma might be due to deficient secretion of suprarenal glands, which causes a hypotonus of the sympathetic nervous system, thus allowing the vagal constituent to obtain the upper hand. Drummond (1923) believes the suprarenal inadequacy to be the fundamental fault in the incidence of asthma. Bray (1931) suggests the possibility of intermittent dysfunction of the suprarenals instead of organic destruction as the characteristic low blood pressure and intense prostration is not present between the attacks.

There is both experimental and clinical evidence in favour of the adrenal deficiency theory. Hajos (1926) finds that sensitiveness in experimental anaphylaxis is increased by thyroid extract and by insulin and is decreased by adrenalin, parathyroid extract and extract of the posterior lobe of the hypophysis. He thinks that clinical anaphylactic sensitiveness and idiosyncratic symptoms are increased in hyperthyroidism, exophthalmic goitre and under insulin and thymus treatment, and is decreased by adrenalin, parathyroid extract and that of the posterior lobe of the hypophysis. Many workers have found that white rats suffering from suprarenal insufficiency are more susceptible than normal rats to histamine, a substance whose actions, both local and general, resemble anaphylactic phenomena so closely. Crivellari (1927) showed that suprarenalectomized rats were 12.5 times more susceptible to histamine phosphate than were normal rats. Marmorston-Gottesman and Gottesman (1928) found that their suprarenalectomized rats were about 20 times more susceptible to histamine-acid-phosphate than were normal rats. Scott (1928) found that most doubly-suprarenalectomized rats were killed by doses that produced only transient symptoms in control rats. Wyman (1928) found that suprarenalectomy or blank operation did not increase the susceptibility of rats to histamine, whereas a double suprarenalectomy increased the susceptibility about 15 times.

Adam (1932) has produced post-mortem evidence to prove the presence of hypo-adrenia in cases of asthma. In a woman of 41, asthmatic for 9 years, necropsy showed that the adrenal medulla was almost wholly destroyed. He quotes two cases of Cameron, one with asthma for 10 years and the other for 20 years, in whom there were similar necropsy findings (almost complete destruction of the adrenal medulla). In one of the three necropsies the cortex was oedematous, in one it contained collections of leucocytes and in the third the whole gland was extremely small.

Cramer and Magee (Adam, 1932) have suggested an explanation for this hypo-adrenia, they have shown that toxic products absorbed from the intestine or elsewhere first stimulate then exhaust the adrenals.

More recently Burn (1933) as a result of his experimental work has drawn attention to a function of adrenalin in the circulation in relation to the sympathetic system. He says the results indicate that the efficiency of the sympathetic nerve (that is to say the size of the response elicited by a given impulse passing down a sympathetic nerve) depends upon the amount of adrenalin in circulation in the blood. In

other words the persons in whom the amount of circulating adrenalin is abnormally low will possess a relatively inefficient sympathetic system and will be predisposed to asthma. Should any chronic inflammatory change develop, leading either to a direct or to a reflex diminution of the bronchiolar airway, those patients will be unable to dilate their bronchioles and will suffer an asthmatic attack. He suggests the addition of some precursors of adrenalin to the diet of asthmatics.

Urinary proteoses.—The ether reaction for proteoses was done in 40 cases with positive results in 36 and negative in 4. The substance was isolated in a group of 9 cases and was used for dermal tests. The dermal tests with each of the 9 proteoses were done on the ease from which it was isolated and on the other 8 cases of the group. No positive result was obtained in any case.

In 3 cases intradermal tests with their own proteoses were tried and in all of these a reaction of inflammatory type was obtained.

The isolation of the urinary proteoses and their use for dermal and intradermal tests was given up, on account of these findings, which, although not extensive, tend to show lack of specificity in the skin reactions with the substance. Moreover, the literature on the subject contains many contradictory statements. While Barber and Oriel (Barber and Oriel, 1928, Oriel and Barber, 1930, Oriel, 1930, 1931 and 1932) are quite definite about the specificity of these proteoses and claim to have obtained remarkable therapeutic results with them, there are other workers (Lyon, Pereival and Stewart, 1932; Freeman, 1932; Cormia, 1933) who refute emphatically the suggestion that they are of any therapeutic value.

Stool findings.—Hookworm ova were found in 5 cases, *Entamoeba histolytica* in 4 and *Bact. pseudo-carolinus* in 3. Enterococci in abundance were found in 20 of the 40 cases and *Bact. lactis aerogenes* in 10. These findings (enterococci and *Bact. lactis aerogenes*) point to intestinal stasis, and this is supported by the presence of indican in the urines of the majority of the cases (37 out of 40 cases had indican in their urine).

Adam (1926) believes the increase in ethereal sulphates to be evidence of intestinal putrefaction; this intestinal putrefaction may give rise not only to such substances such as indol and skatol, which are excreted as ethereal sulphates, but to histamine, which is the one protein derivative known to produce symptoms similar to those of asthma and anaphylactic shock. Clifford Mitchell (Adam, 1926) notes that his most extreme examples of indicanuria were in patients suffering from bronchospasm. He believes that the presence of indican 'in conspicuously large amount in proportion to other normal constituents is almost an infallible sign of a toxic state'. Indican presents only an index of this toxic state, but there may be, as Mitchell points out, other so-far-undiscovered poisons formed in the intestinal canal, which are responsible for the toxic state. Barber and Oriel (1928) in their biochemical investigation of allergic conditions obtained findings similar to those obtained in human cases of intestinal obstruction and in the experimental

intestinal obstruction in animals by Louria (1921) and Haden and Orr (1923).

Evidence of intestinal stasis and pathological conditions of the gut are important, especially in view of the work of Schloss, Walzer and others showing the passage of unaltered food protein from the intestines into the circulation.

Mellanby and Twort (1912) and Hanke and Koessler (1922) demonstrated the presence of histamine-producing organisms in the intestinal tract of man and experimental animals.

Ascoli in 1902 (Walzer, 1927) by means of precipitin reactions detected the presence of egg-white in the blood of normal individuals about 1½ hours after the egg was eaten.

Schloss and Worthen (1916) by means of precipitin and anaphylactic tests showed that the blood of most marasmic infants contains precipitin for cow's milk at some period of the disease, indicating preceding enteral absorption of the antigen-protein from cow's milk. Schloss and Anderson (1922) produced evidence to indicate that under certain conditions the intestinal tract of infants was permeable to slightly altered or unaltered protein. They consider that such passage of unaltered or partially digested protein was specially apt to occur in mal-nourished infants or in those suffering from diarrhoea.

Anderson, Schloss and Myers (1925) found precipitins in the blood of normal infants after the addition of such proteins as cow's milk, egg albumin, sheep serum and almond to their routine diet. In marasmic infants, however, relatively large amounts of the antigenic protein were absorbed and the absorption continued over a much longer period of time than in normal infants, as judged by the degree of precipitin formation and the duration of precipitin in the blood. Walzer (1927) by first passively and locally sensitizing the skin of a person to a particular food with the serum of patients sensitive to that food and then feeding the person with that particular food was able to produce weals at the sensitized site proving the enteral entrance into the blood stream of some of the ingested protein in an unaltered state. He studied the reaction in over 200 individuals and concluded that absorption of such unaltered protein through the intestinal canal is a normal physiological phenomenon.

Bruner and Walzer (1928) using the same methods found that the absorption of detectable amounts of unaltered fish protein from the digestive tract was a normal phenomenon. Sussman, Davidson and Walzer (1928) consider the absorption of amounts of egg protein from the digestive tract as a normal phenomenon.

Lewis and Grant (1926) working independently also proved the absorption of unaltered protein from the digestive tract by the same methods. They obtained serum from an adult markedly sensitive to fish. With this serum they locally sensitized a skin site on a normal subject and 18 hours later fed him with fish. Within an hour, a weal with pruritus and erythema appeared at the passively sensitized site.

Freeman (1925) locally sensitized his middle turbinate bone with the serum of an egg-sensitive patient; later he took egg flip and had itching and an uncomfortable sensation in the nose, thus proving that absorption of unaltered protein into the circulation through the enteral canal could play an important part in the production of paroxysmal rhinorrhoea. Later (1930) he carried out another experiment to show this passage of food-stuffs from the gut into the circulation. The skin of the forearm of two students was injected with a serum from a fish-sensitive patient and into the other forearm he put some of his own serum as control. One student was given a dinner consisting of a considerable amount of fish, the other had no fish. The forearm of the first student became red and swollen where the serum from the fish-sensitive patient had been injected, while the forearm of the

other student did not react at all. Two days later the second student had a cod stake and shortly afterwards developed a most marked reaction.

All the work quoted above conclusively shows the possibilities of absorption of unaltered protein from the digestive tract producing allergic symptoms. The work of Schloss and his co-workers has shown that in the presence of gastro-intestinal disturbances relatively large amounts of the antigenic protein are absorbed and the absorption is carried over a much longer period.

Ganghofner and Langer in 1904 (Walzer, 1927) by means of precipitin tests had shown the importance of trauma of the intestinal mucous membrane in adults in connection with the absorption of unaltered protein. O'Keefe (1927) rightly suggests that faulty digestion by producing irritating intestinal contents might cause a change in the permeability of the capillaries in the villi of the small intestine and thus affect the amount and rate of protein absorption.

As regards the second factor, histamine is formed by decarboxylation (splitting off of CO_2) of histidine which is a compound of every protein. It has a most marked toxic action; the fundamental and characteristic feature of its action is its direct stimulant effect on the plain muscles. It also relaxes and increases the permeability of the endothelial cell layer. Barger and Dale (1910) at first isolated it as an active factor of ergot. Later they (1911) isolated the substance from the gut. Since then with other workers they have shown its presence in most of the tissues of the body.

Dale (1929) considers histamine as a 'generally distributed constituent of the cells of the animal body, inert while it remained within the cell, but intensely active in producing local vasodilator reaction when appropriate stimuli release it from the cell into the tissue fluid, either free or in molecular combination of varying complexity'.

A good deal of interest has centered round histamine because of its wide distribution amongst the body tissues and because of the similarity of its local and general reactions to the local and general anaphylactic phenomenon.

From the great similarity between the histamine reaction and the anaphylactic phenomenon—both the local and general reactions—Lewis (1927) postulated a single fundamental cause to explain the two. He concluded that the response in anaphylaxis was due to release of his H-substance (which is either histamine or has histamine-like reaction) by the anaphylactic injury from the sensitized cells. Dale (1929) considers that such a conception fits all the known facts. He thinks that it is only the sensitized cells that react but 'the histamine might be liberated from the reacting cells or anaphylactic injury of the cells of some larger organ, such as the liver, might liberate histamine into the general circulation in such quantity as to produce its effects in the body generally'. So that the presence of histamine and of organisms capable of producing this substance from histidine in the gut might have a far-reaching importance.

Mellanby and Twort (1912) described the presence of histamine in the intestinal wall and isolated a bacterium from the alimentary canal which converted histidine into histamine. They considered the presence of histamine in the gut of pathological importance. Mellanby (1911) considered that the condition of cyclical vomiting in children—a condition included under allergic diseases—might be due to excessive accumulation of substances like histamine in the gut. He carried out an experimental investigation (1916) into the diarrhoeas and vomiting of children and considered histamine of importance in this connection.

Mellanby and Twort (1912) suggested it as a probability that under normal conditions the liver could deal adequately with histamine as it could with the amines, tyrosine and tryptophane, and render it innocuous, but if this defensive mechanism of the liver broke down for any reason, then many toxic symptoms would follow. This suggestion of Mellanby and

Twort has been refuted by the experimental work of Hanke and Koessler (1924) as far as histamine is concerned, as they have shown that this substance is not detoxicated in the liver, but is made physiologically inert during its passage through the intestinal wall. It is very probable that we have to deal with not only the absorption of histamine from the gut but also of various other allied, but so far undiscovered, toxins and that the liver plays an important rôle in their detoxication as there is clear evidence of deficient liver function in allergies. Dale and Richards (1918) pointed out that the action of histamine did not stand by itself but represented in its most characteristic features a type of action common to a large group of poisonous substances of animal or bacterial origin, poisoning of the capillary endothelium being the common factor in the action of all. It is possible and indeed probable that while the liver is not concerned in detoxicating histamine it may be of definite importance in connection with the detoxication of at least some of the other toxins and that the failure of the defence mechanism of the liver leads to grave symptoms due to the poisonous products of intestinal origin passing unchanged into the general circulation.

Hanke and Koessler (1922 and 1924) found histamine-producing organisms in the intestinal tract. They considered histamine to be a normal constituent of the contents of the large intestine of man and concluded that some of the amine was absorbed as such.

Thus the presence of histamine in the gut and its absorption through the intestinal mucosa has been shown to be a normal occurrence, but Mellanby (1916) has shown that the absorption of this substance through the intestinal mucosa differs in different circumstances. It may be that it produces symptoms when produced and absorbed in comparatively very large amounts. But the possibilities of the histamine produced in the gut reaching the circulation in a physiologically active form in amounts to produce symptoms are very few unless there is considerable injury to the intestinal wall or there is deficiency of histaminase, which is a histamine inactivating substance found by Best and McHenry (1930). And then Dale (1929) finds that histamine is practically limited in its action to the immediate neighbourhood of its liberation. He showed that when present in the general circulation it called forth secretion of adrenalin which neutralized its action. Histamine, then, if it reaches the general circulation in an active form, can only act in the presence of deficient adrenal secretion. It does not therefore seem very probable that histamine produced in the gut produces symptoms by its direct action on the far off tissues. But it can act in another way, i.e., by its local action in increasing the permeability of the intestinal mucosa and thus facilitating absorption of specific food proteins, products of protein digestion and toxic substances of bacterial origin which in their turn act on the tissues and produce symptoms. The views of O'Keefe on this point have already been alluded to. In his opinion the faulty digestion, by producing irritating intestinal contents, might cause a change in the permeability of the capillaries in the villi of the small intestine and thus affect the amount and rate of protein absorption. The absorption of larger amounts of antigenic proteins and the continuation of the absorption over much longer periods in infants with gastro-intestinal disturbances than in normals, as found by Schloss, supports this view.

Fractional gastric analysis.—Asthmatics are said to have a tendency to achlorhydria or diminished acidity.

Maxwell (1925), in 30 non-sensitive asthmatics, reports a complete absence of hydrochloric acid in 40 per cent of his cases and in 73 per cent the free acid reading was less than 20. Criepe and McElroy (1928) amongst 36 asthmatics found achylia present in 2 cases, achlorhydria in 10, hypo-acidity (less than 10) in 12, and normal acidity in 12 cases. Hurst (1930) found in 61 adult cases of asthma that curves below

normal occurred in about 20 per cent more asthmatics than normals. In a series of 200 asthmatic children in whom Bray (1931) did a fractional gastric analysis he found that in 9 per cent of the cases there was a complete absence of hydrochloric acid, in 48 per cent there was a pronounced hypochlorhydria, and in 23 per cent a mild hypochlorhydria so that in 80 per cent of these asthmatic children the hydrochloric acid was below normal. Bray points out that the hypochlorhydria in childhood is most frequent in the earlier years of life when food sensitization is most frequent and he suggests that this is one of the methods by which foreign protein gains easy access to the body, the reaction-producing substances not being destroyed in the digestive tract. He advocates the use of hydrochloric acid in the treatment of asthma and other allergic conditions of children.

Acid therapy of allergic conditions had long been advocated by other workers. Bishop (1893) recommended the use of hydrochloric acid in hay-fever as early as 1893. Crip and McElroy (1928) found acid therapy of value in occasional cases of urticaria and Scheer successfully treated eczema in infants and young children with the use of milk acidified with hydrochloric acid.

We did fractional gastric analyses in 30 out of our 40 cases. Hypo-acidity was present in

TABLE IV

Type of cases	Total number	Number in which gastric analysis was done	Hyper-acidity	Normal	Hypo-acidity
Bronchial ..	27	22	11	10	1
Bronchial and gut ..	6	6	3	3	..
Allergic ..	6	2	..	2	..
TOTAL ..	39	30	14	15	1

The ages of the asthmatic individuals in whom gastric analysis was done varied between 20 and 56 years.

Evidence of damaged liver, as shown by the l  vulose tolerance test, was more marked in the cases with hyperchlorhydria than in those with normal acidity (table V).

Fig. 1.—Free hydrochloric acid. The mean readings and the standard deviations in 30 cases.

only one case, there was normal acidity in 15 cases and hyper-acidity in 14 cases. This is shown in table IV and figure 1 gives the mean readings and the standard deviations of those findings.

It is possible that this hyperchlorhydria is due to reflex causes. In all the five cases with marked hyperchlorhydria the increase in the blood sugar after giving l  vulose was always above 30 mgm. per 100 c.cm. and the liver was

enlarged and tender to pressure in three out of the five cases.

TABLE V

Acidity	LÆVULOSE TOLERANCE TEST				
	Total number of cases	Rise below 30 mgm. (normal)	Rise below 30 mgm. but curve rising till the end of two hours.	Rise above 30 mgm. and curve rising	Number of cases in whom liver enlarged and tender to pressure
Hypo-acidity	1	..	1
Normal acidity	15	6	3	6	6
Hyper-acidity	14	3	2	9	8
TOTAL NUMBER OF CASES	30	9	6	15	14

Liver function.—Voegtlin and Bernheim (1911) demonstrated that in experimental anaphylaxis in animals the liver was essential for the development of anaphylactic shock. Weil (1917) showed that the isolated liver of a sensitized dog did not alter the coagulability of the blood with which it was perfused, but if the antigenic substance was added to the blood before it traversed the organ, it passed out with its coagulability either diminished or completely abolished. From this and from the fact that in dogs dying of anaphylactic shock the liver is practically the only organ showing pronounced and gross alteration he concluded that anaphylactic shock in dogs results from the reaction of the sensitized liver to the antigen substance.

Weil and Eggleston (1917) showed that the sensitized liver of the dog when perfused by the antigen mixed with defibrinated blood became intensely swollen and congested. The normal liver presented no change when thus prepared. Manwaring (1910) defined the anaphylactic reaction in dogs as an explosive formation or liberation of vasodilator substances by the hepatic parenchyma. The later work of Manwaring and his co-workers has definitely proved that in dogs sensitization to an antigen is confined almost entirely to the liver cells. Manwaring (1921) found that complete exclusion of the liver prevented the anaphylactic reaction in sensitized dogs. On releasing the ligatures and allowing the blood once more to pass through the liver, a prompt typical anaphylactic fall in blood pressure was produced. Manwaring, Hoespian, Enright and Porter (1925) showed that the typical anaphylactic contractions of the uterus, urinary bladder and intestine which take place during the first two minutes of anaphylactic shock in dogs do not take place on intravenous injections of foreign proteins into dehepatised anaphylactic dogs. They therefore concluded that these smooth muscle contractions are caused by chemical products (hepatic anaphylactoxin) explosively formed or liberated by the anaphylactic liver products and having a histamine-like effect on smooth muscle structures.

Manwaring, Hoespian, O'Neill and Moy (1925) produced additional evidence to prove the existence of hepatic anaphylactoxin by cross-circulation, hepatic transplantation and blood transfusion tests. They showed that if the liver of an anaphylactic dog be transplanted into a normal dog, the normal dog will

show all of the characteristic features of canine anaphylaxis. Manwaring, Reeves, Moy, Schumaker and Wright (1927) have shown by transplantation experiments that smooth muscle structures can be actively immunized against the anaphylactoxin. They, therefore, regard the anaphylactoxin as a secondary antigen, presumably of protein nature and conceivably a denaturation product of primary antigen.

The work of Weil and Manwaring and his co-workers has conclusively shown that the liver was the primary site of anaphylactic shock in dogs. Since their work it has been held that the liver in some way plays an important part in the production of allergic conditions in human beings. Dean (1922) in a case of anaphylactic shock in man found that the chief and essential change was in the liver. The naked-eye and microscopical appearances were very similar to those described by Weil in acute anaphylactic death in dogs. Oriel and Barber (1930) produced evidence of hepatic damage as revealed by the clinical investigation of the blood and urine in both acute and chronic allergic states in human beings. The results of liver-function tests done by Bray (1931) also point to hepatic inefficiency in asthma and other allergic conditions. Dale (1929), while agreeing with Lewis' view that the response in anaphylaxis was due to release of Lewis' H-substance by the anaphylactic injury of sensitized cells, suggests that anaphylactic injury of the cells of an organ like the liver might liberate histamine into the general circulation in sufficient quantity to cause a reaction of the cells in the other tissues not themselves sensitive to the antigen. Dale, further, holds that liberation of histamine alone will not account for all the symptoms and disturbances that occur in anaphylactic shock and allergic states; for example, the diminished coagulability of the blood, which is constantly found during the anaphylactic reactions in all animals, is not produced by histamine, but as a result of hepatic damage by various toxic substances. Dale points out that this fact alone suffices to show that constituents of the liver cells other than histamine are liberated.

Osman (1929) considers that in allergic children the underlying defect is a too-rapid depletion of the glycogen reserves of the liver. According to Cramer, glycogen in the liver is a secretion and it is not secreted in adequate amounts when the liver is damaged. The proteopexic function of the liver, i.e., its power of fixing foreign protein and its derivatives, appears to depend on an adequate supply of glycogen. When this is inadequate the foreign protein tends to pass the barrier of the liver and enter the general circulation. In this connection it is interesting to note that O'Neill, Moy and Manwaring (1925) found that glycogen disappears almost quantitatively from the canine liver during the first fifteen minutes of anaphylactic shock and McGuigan and Ross (1915) observed a reduction of liver glycogen during peptone poisoning.

There are a number of tests in vogue to test the functional efficiency of liver, but there is no single test that will indicate the state of the functional activity of the organ as a whole, because the liver has multifarious functions to perform; for example it is concerned with metabolism of carbohydrates and fats, with excretion of bile and with regulating the composition of the blood and it exerts a detoxicating effect. The test for any one function, as Sir Humphrey Rolleston (1931) points out, though giving that particular information, cannot therefore be expected to throw light on the other functional activities of the organ. Another difficulty in interpreting the results of hepatic function tests is the great reserve and regenerating powers

that the liver possesses. Mann (Dodds, 1931) produced a permanent reduction of 70 per cent of the functioning liver in dogs and was unable to detect any evidence of diminished function in these animals. Sir Humphrey remarks that after damage to the liver, for example in subacute atrophy, compensatory regeneration rapidly takes place and the functional efficiency of the organ is more or less restored.

The results of a number of tests taken together might give some information about the functional efficiency of the liver, with this view we carried out the following tests in the patients investigated, the icterus index and van den Bergh test, the lævulose tolerance test, the adrenalin test, and the test for urobilin in urine.

Icterus index.—This test gives the amount of bile pigment in the serum. A high icterus index denotes the inability of the liver to excrete the bile pigment wholly or in part, and is due either to damage to the liver or to increased blood destruction, or to both. The index will also be high if the patient is taking carrots, as carotin—the colouring matter in carrots—gives a deep colour to the serum. The icterus index test was first described by Bernheim (1924).

Technique.—About 5 c.c. of blood is withdrawn from a vein, is allowed to stand till the clot begins to separate and is then centrifugalized. The clear serum is removed with a pipette and compared in a colorimeter with a 1 in 10,000 solution of potassium bichromate. The cup containing the standard is kept at a fixed level say 15 or 20 and the one containing the serum is moved up and down till it matches the standard. The reading of the standard divided by the reading of the serum gives the icterus index. If the colour of the serum is too deep, it is necessary to dilute it with normal saline and the result is multiplied by the number of dilutions.

Lævulose tolerance test.—This test was first introduced by Strauss in 1901 to test the absorption power of liver for carbohydrates. He gave 100 grammes of lævulose by mouth and collected the urine for the following 24 hours; the appearance of sugar in the urine was considered as a sign of defective liver function. This did not give very satisfactory results and Shirokauer substituted the estimation of blood sugar in place of urinary sugar. In a normal person there should be little or no rise in blood sugar one hour after taking lævulose by mouth. Spence and Brett (1921) take a rise of 20 mgm. in blood sugar after ingestion of 50 grammes lævulose as a proof of liver inefficiency. Tallerman (1923) considers that if the actual rise in value from the original level exceeds 30 mgm. a degree of liver inadequacy should be presumed. The prolongation of the curve, i.e., a high blood-sugar value persisting at the end of 1½ to 2 hours, is strong evidence of such inadequacy. According to Elmer and Scheps (1930) in normal persons the maximum rise of blood sugar above fasting had never exceeded 20 mgm.

We have been giving a uniform dose of 100 mgm. lævulose to our cases (all adults). The patient gets nothing in the morning, the blood from a vein is taken to determine the fasting blood-sugar level and he is given lævulose dissolved in water to drink. Blood is again taken at the end of 1 and 2 hours.

The adrenalin liver-function test.—A subcutaneous injection of adrenalin normally raises the blood sugar, but fails to do so after hepatectomy, and has relatively little effect when the hepatic glycogen stores are exhausted, for example in starvation, showing that the rise in the blood sugar after the adrenalin injection is due to its action on the glycogen of the liver. In normal persons, after a subcutaneous injection of 0.5 c.cm. of a one-in-a-thousand solution of adrenalin chloride, the average rise in blood sugar is 30 to 40 mgm. above the fasting level. In liver dysfunction there is a very slight rise. A sample of blood is taken in the morning before the patient takes anything, adrenalin is then injected, and samples of blood removed ½ and 1½ hours afterwards.

Urobilin excretion in urine.—McMaster and Elman (1925) and Elman and McMaster (1925) proved experimentally that the formation of urobilin and its presence in faeces and bile directly depend upon the entrance of bile into the intestine. If the bile is not allowed to enter the intestine, disease of, or damage to, the liver cells will not lead to the presence of urobilin in the urine. Bilirubin on entering the intestine is changed by means of bacterial decomposition into urobilogen. The urobilogen thus formed in the intestine is eliminated, mostly with the faeces, as stercobilin. Some of it is absorbed and carried to the liver, to be taken out of the circulation again by the liver cells and to be secreted partly into the bile. The liver cells, when damaged, lose the power of dealing with the urobilogen that is absorbed from the intestine, this unchanged urobilogen is excreted in the urine giving rise to urobilinuria. So that diseased liver cells give rise to urobilinuria, not by making urobilogen but by failing to eliminate the urobilogen formed in the intestine and absorbed therefrom. Urobilinuria occurs with a far less degree of liver injury than does bilirubinuria, so that in liver diseases urobilinuria precedes bilirubinuria. Wallace and Diamond (1925) point out that the degree of interference with the liver function is dependent on the extent and rapidity of the disease process. So that in chronic liver affections, in contrast to the acute states, increase in urobilogen is not found as a constant factor; in slowly progressive liver affection there appears to occur a gradual adaptation of the liver substance to carry on its functions. They, therefore, think that in the chronic stage of biliary diseases neither the urobilogen in the urine nor the bilirubin in the serum show any deviation from the normal in the majority of instances, these tests being significant only in acute cases. Sir Humphrey Rolleston (1931) expresses the same opinion about all the liver-function tests, he says that it is in the acute rather than in the chronic disease of the liver that functional tests are likely to give constant evidence of impaired activity.

Increased blood destruction in the body is another condition that gives rise to urobilinuria. In cases of hæmolytic diseases, Elman and McMaster think that liver damage may be partly responsible for the urobilinuria, but the determining factor is the presence in the intestine of an unusually large amount of bile pigment. Urobilinuria during increased blood destruction is thus a secondary manifestation of increased bile formation due to liberation of increased amounts of hæmoglobin. A large amount of bilirubin enters the intestine and gives rise to the formation of a large amount of urobilogen, which is absorbed in too large a quantity to be adequately dealt with by the liver. The result is that the urobilogen which has not been dealt with by the liver escapes into the general circulation and is excreted by the kidney into the urine.

In the case of complete obstruction of the bile duct no bilirubin will enter the intestine and consequently no urobilogen will be formed. So that in persons with complete obstruction of the bile duct there will be

no urobilinuria even with severe damage to the liver cells or a severe blood destruction or both.

The clinical observation of jaundice would be the most convincing evidence of liver dysfunction, but this is not often present. In our series of 40 cases jaundice was present only in one case. In this case the icterus index was 11, van den Bergh test was negative, the liver was enlarged and tender, the l  vulose tolerance and adrenalin tests showed defective liver function and urobilin was present in the urine.

The icterus index.—This was determined in 30 cases; in 25 cases it was below 6 and only in 5 cases above 6. In all the cases in which the index was above 6 the l  vulose tolerance test showed defective liver function. The indirect van den Bergh test was positive in 3 out of the 5 cases with an icterus index above 6.

The van den Bergh test.—The direct van den Bergh was not positive in any case. The indirect test was positive in 9 cases. In 5 out of the 9 cases the l  vulose tolerance test showed defective liver function, while the adrenalin test indicated deficient function in only 2.

Adrenalin test.—This was done in 38 cases. In 23 cases the rise in blood-sugar level was below 30 mgm., varying from 0 to 29 mgm., the average rise in these cases being less than 15 mgm. per 100 c.cm. of blood. In 15 cases the rise was 30 or more mgm., varying from 30 to 53, the average rise being about 40 mgm. per 100 c.cm. of blood. So that the adrenalin test showed defective glycogenic function in 23 out of the 38 cases tested.

Bray (1931) did the test in 55 asthmatic children and found evidence of liver dysfunction in 23 cases. The relation between the results obtained by the adrenalin test and those by the l  vulose tolerance test are shown in table VI. It will be seen that amongst the 23 cases in which the adrenalin test indicates liver dysfunction, there are 17 cases in which the l  vulose test also indicates liver dysfunction.

TABLE VI

Adrenalin test	Number of cases	L��VULOSE TOLERANCE TEST	
		Defective	Normal
Adrenalin test indicates defective liver function.	23	17	6
Adrenalin test indicates normal liver function.	15	11	4

L  vulose tolerance test.—This was done in 38 cases. The results were normal in 10 cases, the rise in blood-sugar level being below 30 mgm. and the blood-sugar value returning to normal at the end of 2 hours. The average rise in these cases was 14.4 mgm. per 100 c.cm.

In 28 cases the test indicates liver deficiency, in 20 cases the rise was above 30 mgm. and was maintained till the end of 2 hours, the average rise being 43 mgm., in 8 cases the rise was below 30 mgm. but still it was maintained till the end of 2 hours, the average rise in these cases being 16 mgm. per 100 c.cm. These results are shown in figures 2, 3 and 4. So that in

mgm of sugar
per 100 c.c. of blood.

FIGURE 2.

Fig. 2.—The mean readings and the standard deviations in the 20 cases showing a rise in the blood sugar of 30 mgm. or more. The cases have been divided into two groups, 8 in which the initial blood sugar was 80 mgm. or over, and 12 in which it was 75 mgm. or less. There were 6 bronchial cases in the first group and 9 in the second.

34 out of the 38 cases investigated liver dysfunction was shown either by the lævulose test or the adrenalin test or by both.

Clinical observations.—Enlargement and tenderness of the liver was present in 15 of the 40 cases. In 13 out of these 15 cases,

Fig. 3.—The mean readings and the standard deviations in 8 cases in whom the rise in blood sugar was below 30 mgm. but the curve was a rising one till the end of two hours.

Fig. 4.—The mean readings and the standard deviations in 10 cases in whom the lævulose tolerance test was normal. The rise was below 30 mgm. and the initial level was restored at the end of two hours.

other evidence of liver dysfunction was present; in 7 cases both the lævulose and the adrenalin test, in 3 cases only the lævulose test, and in the remaining 15 only the adrenalin test suggested defective function. Thus there was no correlation between the results of the adrenalin and lævulose tests and liver enlargement.

Of the 9 positive van den Bergh tests 5 were in these 15 cases with liver enlargement and 4 were in the remaining 25 cases. Similarly these 15 cases of liver enlargement included 3 cases with an icterus index above 6, in the remaining 25 cases the icterus index was above 6 in only 2 cases. So that it is possible that there is some correlation between enlargement of the liver and a positive van den Bergh test and a high icterus index.

Urobilin in the urine.—Urobilin was present in 19 cases; amongst these 10 showed defective lævulose and adrenalin tests, 2 defective lævulose test and 5 defective adrenalin test; in the remaining 2 cases there was no evidence of liver dysfunction other than urobilinuria.

The results with the five tests for liver dysfunction show that the lævulose tolerance test gives evidence of liver dysfunction in the highest number of cases, then comes the adrenalin test, and the finding of urobilin in the urine (lævulose tolerance in 28 out of 38 cases, adrenalin test in 23 out of 38 cases and urobilinuria in 19 of the 40 cases), whereas the icterus index and the van den Bergh test give positive results in very few cases.

Although the lævulose tolerance test gave evidence of liver dysfunction in a greater number of cases than many other tests yet in many cases where a positive result was expected we got negative results. For instance of all the cases we expected evidence of liver dysfunction in those who had *Entamæba histolytica* or hookworm infection in their gut, but these were the cases where such evidence was obtained in the least number of cases. Amongst 8 such cases the lævulose test was abnormal only in 3, as will be seen from table VII.

It is possible and probable that in some of these cases liver dysfunction was present but was not detected by the lævulose test. Radhakrishna Rao (1933) reports some cases with definite clinical evidence of liver disease giving negative results with the lævulose tolerance test.

A perusal of table VII shows that the ages in all the three patients with *histolytica* or hookworm infection showing an abnormal lævulose test was 35 years and above.

While in the other 5 cases where *histolytica* or hookworm infection was not associated with an abnormal lævulose test the age was above 35 years only in one case, being between 22 and 30 in the other 4. In other words in the 4 patients above 35 years the lævulose test was abnormal in 3 while in the other 4 between 22 and 30 years it was not abnormal in a single case. The same correlation between the abnormal lævulose test and the age incidence is apparent when all the 38 cases in which the lævulose test was done are taken into consideration. Amongst the 28 patients showing a defective lævulose test the ages were above 30 years in 20 cases and below 30 in 8 cases.

TABLE VII

Number	Stool findings	Age	Lævulose tolerance	Liver
1	<i>Entamæba histolytica</i> , <i>Entamæba coli</i> and <i>Giardia</i> cysts.	35	Defective	Enlarged and tender.
2	Hookworm	39	Do.	Do.
3	Do.	42	Do.	Do.
4	Do.	36	Normal
5	Do.	30	Do.
6	Hookworm and <i>Entamæba histolytica</i> cysts.	24	Do.
7	<i>Entamæba histolytica</i> , vegetative and cysts.	26	Do.	Palpable.
8	Hookworm	22	Do.	Palpable and tender.

While amongst the 10 patients showing normal lævulose test the age was above 30 in 5 cases and below 30 in the other 5.

This suggests that there is an increase in the incidence of an abnormal lævulose test with increase in age. This correlation is also evident when we compare our results with those of Bray. Bray (1931) in 55 children got an abnormal lævulose test in 23, i.e., in about 42 per cent of his cases. While in our series of 38 cases an abnormal test was obtained in 28, i.e., in about 74 per cent. It may be that in the younger age the margin of safety in the liver is much more than in adults, so that a greater amount of hepatic damage or dysfunction is required in these cases than in the adults, to give an abnormal lævulose test.

We have not investigated enough cases to be able to say whether or not the gut cases show a greater amount of liver dysfunction than the bronchial cases, but it is clear that in a large percentage of the cases of bronchial asthma evidences of liver dysfunction and intestinal stasis can be obtained.

What part do liver dysfunction and intestinal stasis play in bronchial cases, i.e., the cases secondary to some infection or disease of the respiratory passages?

McDowall (1930) has shown that the introduction of some foreign protein into some animals causes a greatly increased sensitivity of the vagus. In such animals response to an injection of pilocarpine is enormously enhanced and a dose which normally would have little effect may almost kill the animal. Stolar Sherwood and Woodbury (Bray, 1931) found that the excitability of the vagus was increased by previous injections of foreign sera. Freud and Gottlieb (Bray, 1931) found that the peptone or foreign serum caused an enormous increase in the salivary response to pilocarpine.

Eppinger and Hess (McDowall, 1930) showed that asthmatics were unduly sensitive to pilocarpine—the

drug by which the stimulation of the vagus can most conveniently be brought about. The work of Walzer and Schloss has shown the possibilities of enteral absorption of unaltered food proteins.

Pickering (McDowall, 1930) has shown that inadequately digested protein might enter the blood in such quantities as to effect coagulation of blood. Eustis (Bray, 1931) collected 121 cases of spasmodic bronchial asthma associated with intestinal toxæmia and suggests that toxic amines formed by intestinal putrefaction are split up by normal individuals and that asthmatics have lost that power.

It is possible that foreign proteins absorbed from the intestine and entering the general circulation, on account of inadequate proteopexic function of the liver, enhance the sensitivity of the vagus, so that stimuli which would be without effect in normal people cause bronchial spasm. The proteins may be absorbed not only from the intestines but also from the respiratory tract itself or bacterial proteins from any focus of infection in the body may gain access to the general circulation.

Apart from the action on the sensitivity of the vagus nerve, foreign protein in common with the toxins absorbed from the gut has a locally constricting effect on the bronchial musculature. The patients in whom the attack of asthma is due to direct chemical action of the substances absorbed from the gut on the bronchial musculature will be relieved by an injection of adrenalin; we have classed these as cases of gut origin. The patients in whom the attacks are due to bronchial constriction brought about by direct or reflex stimulation of the vagus (whose activity has been heightened by protein absorption) will derive benefit from a subcutaneous injection of atropine. Atropine will have no effect in cases in which there is direct action on the bronchial musculature.

Summary and conclusions

(1) Results of the biochemical investigation in 40 cases of asthma are reported.

(2) Pande's adrenalin test for sympathetico-tonia gave no useful information. The reaction was normal in all the cases.

(3) The blood sugar and the systolic blood pressure was generally low and this seems to be due to hypo-adrenia.

(4) The ether reaction for proteoses was done in 40 cases with positive results in 36. Dermal tests with auto-proteoses and with proteoses separated from other patients were tried in 9 cases with negative results.

(5) Indican was present in the urine of 37 of the 40 cases and enterococci in abundance were present in cultures from the stool in 20 cases. These findings point to the presence of intestinal stasis. The important part which the intestinal stasis plays in bringing about the symptoms has been discussed.

(6) Fractional gastric analysis was done in 30 cases. Hypo-acidity was present in only one case, there was normal acidity in 15 cases and hyper-acidity in 14 cases.

parasites per c.mm. always proved fatal in spite of prompt treatment. In the earlier experiments a course of 3 injections of tebetren in doses of $4\frac{1}{2}$ to 6 grains daily was given by the intramuscular route, but in subsequent experiments injections were given for 4 days. In the intravenous series doses larger than 3 grains for a monkey of average weight (3 to 5 kilogrammes) proved fatal in a number of animals; doses of 3 grains were therefore given in the later experiments.

In the following tables the detailed observations of the effect of tebetren on these animals are recorded :

TABLES

No. I, *Silenus rhesus*, weight 4.540 kilogrammes, inoculated with 0.5 c.cm. blood from a heavily parasitized monkey (count not done) containing rings, trophozoites and schizonts. Incubation period 7 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
2-5-34 3-5-34	Rings 450,000	3 grains i.m.	Rings, growing trophozoites and schizonts. R.B.C. 6,200,000 per c.mm.
4-5-34	466,200	Do.	Trophozoites and schizonts. R.B.C. 5,180,000 per c.mm.
5-5-34	325,000	Do.	Parasites chiefly growing trophozoites. Infected cells showing Schüffner's dots. R.B.C. 5,000,000 per c.mm.
7-5-34	Scanty trophozoites.	Do.	Parasites showing evidence of degeneration. R.B.C. 4,320,000
8-5-34	Scanty	Do.	Degenerating parasites.
9-5-34	Very scanty	Do.	Degenerating parasites. Marked basophilia. R.B.C. 3,800,000 per c.mm.
10-5-34	No parasites.	..	Marked basophilia Normoblasts. R.B.C. 3,800,000 per c.mm.
14-6-34	Parasites (no count).	..	Rings, growing trophozoites and schizonts.
15-6-34	180,000	6 grains i.m.	Rings, growing trophozoites and schizonts. R.B.C. 3,000,000 per c.mm.
16-6-34	90,000	Do.	Normoblasts R.B.C. 1,520,000 per c.mm.
17-6-34	15,000	Do.	Evidence of degeneration in the parasites.
18-6-34	No parasites.	Do.	Basophilia, normoblasts.

Tebetren was given by the intramuscular route in doses of 3 grains daily for 6 days. A low grade of infection persisted for about a month after the cessation of treatment of the primary infection. On 15th June, 1934, there was a relapse with a parasite count of 180,000 per c.mm.; a larger dosage, 6 grains daily for 3 days, completely controlled the infection. No parasites were found in the peripheral blood during an observation period of 5 months.

No. II, *Silenus rhesus*, weight 3.460 kilogrammes, inoculated with 1 c.cm. of heavily parasitized blood. Incubation period 8 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
25-5-34	140,000	6 grains i.m.	Rings and trophozoites. R.B.C. 4,600,000 per c.mm.
26-5-34	80,000	Do.	R.B.C. 4,000,000 per c.mm.
28-5-34	?	Do.	Evidence of degenerative changes in the parasites.
29-5-34 to 26-7-34	No parasites.

Two tablets of tebetren daily intramuscularly for 3 days completely controlled the infection. Degenerative changes of the parasites were marked after the second injection and they disappeared after the third injection. No parasites could be detected in the peripheral blood afterwards for an observation period of nearly 2 months. The monkey died on the night of 26th July, 1934, probably as a result of some intercurrent infection. Smear from heart's blood showed no parasites.

No. III, *Silenus rhesus*, weight 3.510 kilogrammes, inoculated with 0.5 c.cm. blood containing 275,000,000 parasites. Incubation period 4 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
11-6-34	100,000	..	Rings and growing trophozoites
12-6-34	1,000,000	6 grains i.m.	Rings, trophozoites and schizonts.
13-6-34	425,700	Do.	Do.
14-6-34	23,350	Do.	Degenerating parasites. R.B.C. 4,670,000 per c.mm.

Treatment was started in this case when the parasite count was very high, i.e., 1,000,000 parasites per c.mm. The parasites were nearly halved 24 hours after the first injection and completely disappeared from the peripheral blood after a course of 3 injections (6 grains daily for 3 days). A relapse occurred 12 days after this like that observed in cases treated with atebren, and proved fatal. A smear from heart's blood showed that almost every red cell was infected, many showing multiple infection. This is the only animal in our series of experiments in which a relapse proved fatal.

No. IV, *Silenus rhesus*, weight 3.695 kilogrammes, inoculated with 1 c.cm. blood containing 405,900,000 parasites. Incubation period 5 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
26-6-34	778,000	6 grains i.m.	Parasites mostly rings. R.B.C. 5,190,000 per c.mm.
27-6-34	625,500	Do.	All forms of parasites, rings, trophozoites, schizonts and gametocytes. R.B.C. 4,270,000 per c.mm.
28-6-34	Scanty	Do.	Evidence of degenerative changes in the parasites. R.B.C. 4,190,000 per c.mm.
29-6-34	No parasites.	..	Commencing basophilia. Demilune cells.
9-7-34	Scanty	..	Rings.
12-7-34	357,000	6 grains i.m.	Mostly rings. Few growing trophozoites. R.B.C. 5,100,000 per c.mm.
13-7-34	414,000	Do.	Mostly growing trophozoites, few rings. Evidence of degeneration in the parasites. Commencing basophilia. R.B.C. 4,600,000
14-7-34	67,500	Do.	Degenerative changes in the parasites.
16-7-34	No parasites.	Do.	Basophilia, normoblasts.

This animal received a course of 3 injections (6 grains daily) when the parasite count was fairly high. A relapse occurred in ten days, all stages of parasites being found in the peripheral blood. A longer course of 4 injections was given (6 grains daily); the parasites disappeared and were not found again in the peripheral blood during an observation period of 4 months.

No. V, *Silenus rhesus*, weight 3.720 kilogrammes, inoculated with 0.5 c.cm. blood containing 173,100,000 parasites. Incubation period 5 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
3-7-34	130,000	..	Parasites mostly rings.
4-7-34	700,000	6 grains i.m.	Rings and growing trophozoites. R.B.C. 5,000,000 per c.mm.
5-7-34	1,009,800	Do.	Mostly growing trophozoites and schizonts. R.B.C. 4,590,000 per c.mm.
6-7-34	80,000	Do.	Parasites showing degenerative changes.
7-7-34	No parasites.	Do.	Commencing basophilia, normoblasts.

Treatment was started when the parasite count was fairly high, i.e., 700,000 parasites per c.mm. A course of 4 injections (6 grains daily) was given from the beginning instead of three as in the previous experiments. In this case the first injection had no effect on the parasites and the count rose above 1 million on the second day; it came down subsequently and the parasites disappeared after 3 injections. Degenerative changes in the parasites were well marked after 2 doses. This animal was under observation for more than 4 months after the cessation of treatment, and frequent examinations of the blood did not show any parasites. In this respect the action of tebetren resembled that of quinine.

No. VI, *Silenus rhesus*, weight 5 kilogrammes, inoculated with 1 c.cm. blood containing 700,000,000 parasites. Incubation period 5 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
11-7-34	931,000	6 grains i.m.	Rings and growing trophozoites. R.B.C. 4,900,000 per c.mm.
12-7-34	491,000	Do.	All forms of parasites including gametocytes. R.B.C. 4,910,000 per c.mm.
13-7-34	Scanty	Do.	Evidence of degenerative changes in the parasites.
14-7-34	Do.	Do.	Do.
15-7-34 to 15-11-34	No parasites.

This monkey was given a course of 4 injections, 6 grains daily. After 2 injections the parasites showed degenerative changes, their number being considerably reduced; scanty degenerating forms were found for the next two days. Subsequently the peripheral blood remained free of parasites (similar to monkeys II and V).

No. VII, *Silenus rhesus*, weight 4.560 kilogrammes, inoculated with 0.5 c.cm. blood containing 221,200,000 parasites. Incubation period 5 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
20-8-34	260,000	..	Rings and growing trophozoites.
21-8-34	688,500	6 grains i.m.	All forms of parasites. R.B.C. 5,100,000 per c.mm.
22-8-34	1,260,000	Do.	All forms of parasites, apparently healthy. R.B.C. 4,500,000 per c.mm.

This monkey was given the drug intramuscularly when the parasite count was fairly high. The count rose to above 1 million in spite of treatment (1,260,000 parasites per c.mm.), a condition hardly compatible with life.

No. VIII, *Silenus rhesus*, weight 3 kilogrammes, inoculated with 0.5 c.cm. blood containing 344,250,000 parasites. Incubation period 5 days.

In this monkey treatment was started on 27th August, 1934, when the parasite count was above 1 million (1,200,000 parasites per c.mm.) in order to see whether the drug had any effect in such a heavy infection; $4\frac{1}{2}$ grains of tebetren was given intramuscularly. The monkey died on the same night. Smears from liver and heart's blood showed that these organs were crammed with parasites, nearly 80 per cent of the red cells being infected.

No. IX, *Silenus rhesus*, weighing 3.100 kilogrammes, was inoculated with 0.25 c.cm. blood containing 300,000,000 parasites. Incubation period 5 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
3-9-34	561,000	3 grains i.m.	Rings and growing trophozoites R.B.C. 5,100,000 per c.mm.
4-9-34	133,500	Do.	All stages of parasites. R.B.C. 4,450,000 per c.mm.
5-9-34	Scanty	Do.	Evidence of degenerative changes in the parasites.
6-9-34	Do.	Do.	Evidence of degenerative changes in the parasites. Basophilia, normoblasts.

This animal received a course of 4 injections (3 grains daily). Very scanty parasites however persisted in the blood for a week after cessation of treatment; on the eighth day the count again rose to 120,000 parasites per c.mm. The multiplication of parasites was however less rapid and the count gradually came down without further treatment. Subsequent to this the peripheral blood remained mostly free of parasites.

No. X, *Silenus rhesus*, weight 4.730 kilogrammes, inoculated with 0.5 c.cm. blood containing 70,000,000 parasites. Incubation period 7 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
2-6-34	300,000	$4\frac{1}{2}$ grains i.v.	Rings and growing trophozoites R.B.C. 5,010,000 per c.mm.
3-6-34	160,000	Do.	R.B.C. 4,100,000 per c.mm.
4-6-34	Scanty	Do.	Degenerating parasites.
5-6-34	Do.
6-6-34	Do.
8-6-34	Parasites ++ (count not done).
9-6-34	219,000	$4\frac{1}{2}$ grains i.v.
11-6-34	22,500	Do.	Few rings, mostly trophozoites.
12-6-34	Scanty	Do.	Degenerating parasites.

In this animal the infection was controlled with doses of $4\frac{1}{2}$ grains daily for 3 days intravenously. Though the primary infection was controlled with this course of treatment, it was not sufficient to prevent the rapid multiplication of parasites within a very

short time (4 days). The parasites again appeared in the peripheral blood 12 days after the second course of tebetren, but this time they multiplied less rapidly and gradually disappeared even without treatment. This animal was under observation for a period of over 4 months after the cessation of treatment, and the peripheral blood remained free of parasites during the period.

No. XI, *Silenus rhesus*, weight 3 kilogrammes, inoculated with 0.5 c.cm. blood containing 150,000,000 parasites. Incubation period 3 days.

This monkey died within five minutes of an intravenous injection of $4\frac{1}{2}$ grains of tebetren. As this dose was toxic, the dosage by the intravenous route was reduced in the subsequent experiments.

No. XII, *Silenus rhesus*, weight 3.880 kilogrammes, inoculated with 1 c.cm. blood containing 1,000,000,000 parasites. Incubation period 7 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
20-6-34	405,900	3 grains i.v.	Rings and growing trophozoites. R.B.C. 4,510,000 per c.mm.
21-6-34	500,800	$4\frac{1}{2}$ grains i.v.	Rings and growing trophozoites R.B.C. 4,590,000 per c.mm.
22-6-34	480,000	Do.	All forms of parasites including gametocytes. Evidence of degenerative changes. R.B.C. 4,000,000 per c.mm.
23-6-34	40,000	Do.	Degenerating parasites.
24-6-34	Scanty parasites.
25-6-34	No parasites.
1-7-34	155,200	$4\frac{1}{2}$ grains i.v.	Rings and trophozoites.
2-7-34	83,750	Do.	Parasites appear to be healthy.
3-7-34	Scanty	$4\frac{1}{2}$ grains i.m.	The injection was given intramuscularly because of the difficulty of finding a suitable vein after repeated i.v. injections.
4-7-34	No parasites.	6 grains i.m.	Basophilia, poikilocytosis, normoblasts, etc.
19-7-34	Rings ++
20-7-34	118,800	6 grains i.m.	Mostly growing trophozoites, a few schizonts. R.B.C. 4,000,000 per c.mm.
21-7-34	68,200	Do.	Evidence of degeneration. R.B.C. 3,410,000 per c.mm.
22-7-34	No parasites.	Do.	Basophilia, normoblasts.
23-7-34	Do.	Do.	Do.

This animal was given a course of 4 injections intravenously. The parasites disappeared after the

fourth injection (usually after 2 injections by the intramuscular route). A relapse or recrudescence occurred 5 days after the treatment of the primary infection and again a fortnight after the second course of tebetren, for which tebetren was given partly intravenously and partly by the intramuscular route. A low grade of infection persisted for about 2 months but the parasites never multiplied rapidly. Subsequent to this the peripheral blood showed no parasites.

No. XIII, *Silenus rhesus*, weight 3.610 kilogrammes, inoculated with 0.5 c.cm. blood containing 389,000,000 parasites. Incubation period 6 days.

This monkey received 4½ grains of tebetren intravenously. Immediately after the injection the animal had convulsions with spasmodic respiration and died within half an hour (see also monkeys XI and XIV).

No. XIV, *Silenus rhesus*, weight 4.290 kilogrammes, inoculated with 0.5 c.cm. blood containing 465,500,000 parasites. Incubation period 7 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
19-7-34	395,200	4½ grains i.v.	Mostly rings, few growing trophozoites.
20-7-34	125,000	Do.	R.B.C. 6,080,000 per c.mm. Rings and trophozoites. The animal had convulsions of the whole body immediately after the injection. Died after ten minutes.

It has already been shown that a dosage larger than 3 grains intravenously proves toxic for these animals. In this case though the parasite count came down appreciably after the first injection, the animal succumbed after the second dose.

No. XV, *Silenus rhesus*, weight 4.100 kilogrammes, inoculated with 0.5 c.cm. blood containing 197,600,000 parasites. Incubation period 7 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
27-7-34	Rings and growing trophozoites
28-7-34	276,000	3 grains i.v.	Rings and trophozoites. R.B.C. 6,140,000 per c.mm.
29-7-34	770,900	Do.	All forms of parasites including gametocytes. apparently healthy. R.B.C. 5,930,000 per c.mm.
30-7-34	58,500	Do.	Evidence of degenerative changes in the parasites. R.B.C. 4,000,000 per c.mm.
31-7-34	Scanty	Do.	Degenerating parasites. R.B.C. 3,800,000 per c.mm.
3-8-34	Do.	Do.

In this monkey the dose of tebetren by the intravenous route was reduced to 3 grains and was well tolerated. The parasite count came down appreciably after 3 injections, but a low grade of infection persisted for more than 6 months for which no treatment was necessary as the parasites never multiplied rapidly.

No. XVI, *Silenus rhesus*, weight 4.159 kilogrammes, inoculated with 0.5 c.cm. blood containing 138,000,000 parasites. Incubation period 6 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
4-8-34	102,000	3 grains i.v.	Mostly rings and growing trophozoites. R.B.C. 5,100,000 per c.mm.
5-8-34	162,000	Do.	All stages of parasites. R.B.C. 5,400,000 per c.mm.
6-8-34	42,000	Do.	Degenerating parasites. R.B.C. 4,200,000 per c.mm.
7-8-34	20,000	Do.	Degenerating parasites.
8-8-34	Scanty	..	Do.

In this animal the infection was controlled after the fourth injection of tebetren intravenously. Rapid multiplication of the parasites occurred from the fifth day after cessation of treatment of the primary infection which was controlled with 3 more intravenous doses (3 grains daily). Though a relapse occurred 18 days after this, the multiplication of the parasites was less rapid and they disappeared without any further treatment.

No. XVII, *Silenus rhesus*, weight 5.216 kilogrammes, inoculated with 0.5 c.cm. blood containing 51,000,000 parasites. Incubation period 7 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
13-8-34	Rings and trophozoites ++
14-8-34	442,400	3 grains i.v.	All stages of the parasites. R.B.C. 5,530,000 per c.mm.
15-8-34	90,000	Do.	All stages of the parasites. R.B.C. 4,500,000 per c.mm.
16-8-34	174,000	Do.	Parasites are apparently healthy. R.B.C. 4,350,000 per c.mm.
17-8-34	Scanty	Do.	Degenerating parasites.

30-8-34	10,000
1-9-34	Scanty	..	Degenerating parasites. Basophilia, normoblasts.

In this monkey the parasite count came down after 3 intravenous injections, scanty parasites however persisting. Five days after the cessation of treatment, the parasites multiplied rapidly and the count rose to 280,000 parasites per c.mm. No treatment was given for this; though the infection persisted for more than a month, the parasite count gradually came down. Later during an observation period of about 3 months, the peripheral blood remained mostly free of parasites (see also monkeys IX, X and XVI).

Discussion

A perusal of the foregoing tables will show that in monkeys I to IX tebetren was administered intramuscularly while in monkeys X to XVII it was given intravenously. The drug undoubtedly has a destructive effect on *Plasmodium knowlesi* infection in these animals whether it is given by the intramuscular or the intravenous route. Dosage of $4\frac{1}{2}$ to 6 grains daily for 2 to 3 days by the intramuscular route and 3 grains daily intravenously for 3 to 4 days controlled a heavy infection which amounted to as much as a million parasites per c.mm. In the majority of the animals its action was immediate; the parasites usually decreased in numbers after the first injection or, even when they did not decrease, their multiplication stopped or was considerably inhibited. In this respect the drug differed somewhat from quinine which, in our experiments described in a previous paper (1934), did not so promptly stop or inhibit the growth of the parasites after the first injection, but often appeared actually to accelerate their multiplication. This increase in the number of parasites in the peripheral blood was also observed after intravenous injection of quinine in man by Chopra and his co-workers (1932). It will also be observed that in some animals of this series, after a full course of treatment of the primary infection, the plasmodia disappeared from the peripheral blood entirely (nos. II, V and VI), while in

others they reappeared after an interval, producing a relapse (nos. I, III, IV, XII and XVI) and in no. III the relapse proved fatal in spite of treatment.

Dosage.—Monkeys weighing between 3 to 5 kilogrammes tolerated a dose of $4\frac{1}{2}$ to 6 grains dissolved in $1\frac{1}{2}$ to 2 c.cm. of distilled water by the intramuscular route without any untoward effects; no local reactions were observed. The number of injections necessary to free the peripheral blood from plasmodia varied from 3 to 4, and this was effective in controlling a heavy infection (nos. III, IV, V and VI). By the intravenous route a dose of 3 grains could be administered safely, but doses larger than this proved fatal and three animals died after injections of $4\frac{1}{2}$ grains of tebetren (nos. XI, XIII and XIV). Doses of 3 grains in animals weighing 4 to 5 kilos. appear to be safe and, when compared with the effective therapeutic dose of 24 to 36 grains (8 to 12 tablets a day) for an adult human being weighing 60 to 80 kilos., show that the toxicity of the drug is fairly low.

Intramuscular and intravenous injections.—A study of tables I to IX shows that after a single intramuscular injection of tebetren in most of the cases the plasmodia showed degenerative changes, were quickly destroyed and their number in the peripheral blood showed a considerable decrease. The reduction in the number of parasites appeared after the first injection but was definite and considerable after the second injection. In this respect the effect of tebetren would appear to approach that of atebren, which in our experiments reported in a previous paper (1933) produced a remarkable decrease in the number of parasites as well as marked degenerative changes in their cytoplasm almost immediately. Though the action of this drug was not so rapid as that of atebren, the results were fairly constant and a very heavy infection appeared also to be more amenable to treatment with tebetren than quinine. Intramuscular injections of quinine, it will be remembered, have a gradual action on the parasites and, as a rule, there is no remarkable decrease in their numbers for 24 hours after the first injection or even longer.

The state of affairs after intravenous injection of tebetren, however, was different. Whereas atebren produced similar effects on the parasites whether given by the intramuscular or the intravenous route, the effect of tebetren on the plasmodia when given intravenously was much less evident. The effects observed were variable and undoubtedly much weaker after the first injection; sometimes even after the second injection hardly any changes were noticed. As a matter of fact after the first injection in most of the animals (nos. XII, XV and XVI) there was an actual increase in the number of parasites in the peripheral blood, and as a rule 3 injections were necessary to

reduce appreciably the number of plasmodia. The parasite count increased on the second day in monkeys XV and XVI, decreased in monkey XVII but increased again on the third day; the count in no. XII remained more or less steady for 3 days while only in no. X it came down appreciably from the second day onward. This effect of tebetren may be due to rapid excretion of the drug when given intravenously so that the contact of the drug with the parasites is of shorter duration.

Comparative action of atebtrin, quinine and tebetren

It has already been stated that atebtrin has a powerful immediate effect on *Plasmodium knowlesi*. Even when the parasite count is high, one dose of this compound produces an enormous reduction in the number of the plasmodia and the infection is controlled by whatever route the drug is administered, intramuscular or intravenous. In the case of quinine one dose is only effective when the parasite count is low but in heavy infections two or more injections are necessary. Tebetren would appear to stand between quinine and atebtrin in its action on this plasmodium in so far as the reduction in the number of parasites is concerned. Generally the parasite count is nearly halved 24 hours after an intramuscular injection of atebtrin and degenerative changes are evident after the second injection. By the intravenous route the effects in case of tebetren are less conspicuous and two or three injections are necessary to bring down the parasite count, and in this respect it bears a closer resemblance to quinine.

So far as relapses are concerned, tebetren appears to possess an advantage over atebtrin. After five days' intensive treatment with atebtrin in fairly large doses, the plasmodia invariably reappeared in 10 to 15 days and multiplied with the same rapidity as in the primary attack causing death of the animal if prompt treatment was not given, whereas with tebetren though a relapse or recrudescence occurred in some animals in 5 to 12 days, it did not prove fatal except in no. III. In some of the relapses the animals were kept without treatment intentionally, and the parasites often disappeared spontaneously (nos. IX, X, XVI and XVII). In nos. II, V and VI the parasites disappeared altogether from the peripheral blood after an intensive treatment of the primary infection with this compound and in monkey XV the parasites were scanty, never multiplied and the animal remained healthy without further treatment.

Tebetren chemically is said to be a methylhydrocupreine-methyl-acridine - dihydrocholate, i.e., a compound in which quinine is combined with acridine from which atebtrin is derived. The destructive action of tebetren on *P. knowlesi* infection appears to combine

the virtues of quinine and atebtrin. So far as the control of infection is concerned, it has a powerful and rapid destructive action on the plasmodia, thus resembling atebtrin; reduction in the number of the parasites in the peripheral blood is more rapid than with quinine. With regard to relapses the effects on these animals were very much like those produced in quinine-treated animals inasmuch as the parasites either disappeared spontaneously after a relapse or if they multiplied the multiplication was not so intensive as to cause death of the animal except in one instance. The action of tebetren in human malaria is under investigation but while expressing no opinion regarding the efficacy or otherwise of tebetren on malarial infection in man, we are justified in concluding that this drug has a fairly powerful action on *P. knowlesi*. Intramuscular injections are more effective and better tolerated than intravenous injections, this being probably due to more prolonged contact of the drug with the parasites.

Summary

The results of investigations regarding the action of tebetren on plasmodium infection in *Silenus rhesus* are given. Tebetren is a synthetic drug in which quinine is said to be combined with an acridine dye and bile salts are added to render it less toxic. The results of the experiments on this monkey indicate that tebetren is a fairly efficacious drug in the treatment of infections with *Plasmodium knowlesi*. A dose of $4\frac{1}{2}$ to 6 grains daily for 2 days by the intramuscular route and 3 grains daily intravenously for 3 days controlled fairly heavy infections amounting to as much as a million parasites per c.mm. In so far as the decrease in the number of parasites in the peripheral blood is concerned, tebetren appears to be intermediate in action between atebtrin and quinine. The parasite count is nearly halved 24 hours after an intramuscular injection and degenerative changes in the parasites are evident after the second injection. By the intravenous route, however, the effects are less marked and two or three injections are necessary to bring down the number of parasites in the blood appreciably; in this respect its action resembles quinine.

So far as relapses are concerned, the effects observed resembled more or less those produced in quinine-treated monkeys; the parasites either disappeared spontaneously, or, if they multiplied, the multiplication was slow and except in one case death did not occur. The drug, it seems, combines the virtues of atebtrin and quinine and gives promise of being a useful remedy in the cure of malarial infection. It is on trial on human cases of malaria in the Carmichael Hospital for Tropical Diseases.

THE PASSAGE OF HOOKWORMS AFTER TREATMENT

By P. A. MAPLESTONE, D.S.O., M.B., Ch.B., D.T.M.
and

A. K. MUKERJI, M.B.

(From the Helminthological Research Laboratory,
Endowment Fund, School of Tropical Medicine,
Calcutta)

IN industrial practice the impossibility of keeping under control large numbers of coolies for a prolonged period after mass treatment for hookworm infection has led to the employment of various rough and ready methods of assessing the efficacy of such treatment. One of the commonest of these is to examine for the presence of hookworms the first stool passed after treatment. The senior author has several times been asked what he considered to be the value of this method, and while expressing the opinion it was probably not of much use he always had the feeling he might be wrong, because as far as he knew no definite data on the point were available. It was accordingly decided to investigate this question.

The following method was adopted in the inquiry. Only hospital in-patients were made use of because sufficient supervision of out-patients was impracticable. All the patients were treated by our usual routine method; they were given 3 c.cm. of tetrachlorethylene and 1 c.cm. of oil of chenopodium shaken up in two ounces of saturated solution of magnesium sulphate. The treatment was given at 6 a.m. and from this hour until 6 p.m. on the same day all the stools passed were kept separate and individually examined for hookworms by washing through a fine sieve, the times at which all the stools in this first twelve hours were passed was also noted. From 6 p.m. until 6 a.m. the following morning any stools passed were examined for each patient as a whole and

the same was done for the second, third and fourth twenty-four-hour periods respectively.

One hundred cases treated for hookworm infection in the Carmichael Hospital for Tropical Diseases were dealt with in the above manner. Many of these were only light infections as they had been admitted for conditions other than hookworm infection and the latter was only found in the course of the usual routine examinations. It was noticed that the proportion of lightly infected persons failing to pass worms in the first stool was slightly higher than that of those more heavily infected; this point is discussed below.

Seventy-three patients were cured, but as cure or failure to cure had no bearing at all on the passage of worms in the first stool this aspect has been ignored and cured and uncured cases are discussed together. Cure was considered established if the patient showed no eggs in a direct centrifugal flotation preparation ten days after treatment. Egg counts were done on all the patients before treatment with the idea of gaining an approximate estimate of the number of worms that might be anticipated from each case, but as they showed absolutely no correlation with the number of worms subsequently passed they have not been considered.

Altogether 42 of the patients passed no worms in the first stool and 22 passed the first stool between 6 and 6-30 a.m., that is within half an hour of the treatment being given, and eight of these 22 passed worms in the stool. Of the 14 who did not pass worms in the first stool 5 passed their stools between 6 and 6-15 so it is considered better not to include these 5 as failures to pass worms, as it was such a short time after treatment, therefore of this group we can say that 8 passed worms and 9 failed to do so. As a check on the time that worms might be expected to appear in the stools after treatment those passing their first stool between 6-30 and 8 a.m. were taken separately; there were 26 in this group and 13 passed worms while 13 did not do so. A further check was the taking of those who passed their first stools between 8 and 10 a.m., there were 25 in this group and only 10 of them passed worms in the first stool. From these observations it seems safe to assume that the chance of finding worms in stools passed half an hour after treatment is as good as when the stool is retained for over two hours. Therefore, excluding the 5 who passed stools earlier than 6-20 a.m., we can say that 39 persons failed to pass worms in the first stool, and 27 of these passed less than a total of 20 worms.

It was mentioned above that the proportion of failures to pass worms in the first stool was somewhat greater among the light infections, so a division was made between those passing 1 to 19 worms and those passing 20 or more. Out of 55 lightly infected 28 passed worms and 27 did not (this includes 3 who passed stools

before 6-20 a.m.), and in the 45 with heavier infections 30 passed worms and 15 did not (including 2 who passed a stool before 6-20 a.m.). In the heavy infection group the numbers of worms passed in the first stool in relation with the total number passed are shown in the following list, the left hand figure being the number in the first stool and the right hand one being the total:—0|48, 2|32, 15|27, 1|92, 1|21, 1|36, 2|27, 80|84, 8|29, 7|77, 10|41, 60|67, 234|252, 748|1,249, 92|109, 0|28, 22|27, 32|34, 0|106 (passed at 6-10), 164|199, 219|233, 0|360, 0|31, 0|132, 1|21, 0|27, 0|22, 0|20, 0|29, 0|31, 49|102, 13|66, 182|199, 0|23, 0|157, 0|39, 30|70, 17|82, 4|48, 99|200, 0|112, 18|124, 15|35, 49|94, 651|902.

It is usual for us to give a second dose of magnesium sulphate at 10 a.m. if the bowels have not acted by that time and in the present instance 16 of the cases had to be given this second dose and it was found that the proportion of worms passed in the first stool was considerably higher than the average of the 45 cases shown above, and also 14 of the 16 passed worms in the first stool. Some of the figures in the following list have already been given in the one above and to these have been added the ones who passed less than 20 worms, and needed a second dose of purgative:—49|102, 13|66, 219|233, 0|2, 11|11, 13|19, 164|199, 7|77, 234|252, 10|16, 3|6, 2|2, 32|34, 3|3, 9|10, 0|1.

Although the proportion here is distinctly higher than in the above group it still shows that even after a long delay and the administration of a second dose of purgative by no means all the worms are passed in the first stool. It will be also noted that in this group 3 of the patients passed all the worms in the first stool and were cured, but they only produced 11, 3 and 2 worms respectively. Two other cases were cured that passed all their worms in the first stool, one passing 7 worms at 7-45 a.m., and the other 1 worm at 10 a.m.

Altogether 62 patients passed worms on the second day, and 9 of these had passed no worms on the first day although they all had one or more stools on that day. These 9 were all light infections with the exception of one, and this one had two stools on the first day and passed 127 worms on the second day, followed by 5 on the third. This shows that a delay in passing worms for over 24 hours does not ensure the passage of all in one stool. Another case worthy of special comment is one that passed two stools on the first day with no worms in the first stool and 98 in the second which was passed at 1-10 p.m., this was followed by 243 worms on the second day and 16 on the third day.

Twenty-two patients passed worms on the third day, and in two of these this was the first occasion on which worms were found, but only 2 worms were passed in one case and 1 in the other. Out of 20 patients whose stools were

CONGENITAL HYDRONEPHROSIS DUE TO AN ABNORMAL ATTACHMENT OF THE RENAL FASCIA (OF GEROTA)

By V. MAHADEVAN, F.R.C.S., M.R.C.P. (Edin.)

LIEUTENANT-COLONEL, I.M.S.

and

T. BHASKARA MENON, M.D. (Mad.), M.R.C.P. (Lond.)
Stanley Medical School, Madras

In the series of 100 cases of ureteral obstruction recorded by Hunner (1918) the occurrence of congenital obstruction due to a fascial band has not been recorded. Eisendrath makes no mention of this anomaly in his studies on congenital strictures.

Obstructions of the ureter may be classified as due to *ureteral* and *extra-ureteral* causes.

(Continued from previous column)

examined on the fourth day 2 passed one worm each and one passed 3 worms.

Disintegration of worms that have been killed by an anthelmintic is fairly rapid in the intestine so it is probable that many more worms were passed than could be recognized as such, especially on the second, third and fourth days. Against this fact it might be advanced that as worms were found on these three days disintegration cannot have been very rapid. The probable explanation of this is that we have found (contrary to the usual opinion) that the majority of worms evacuated as a result of tetrachlorethylene and oil of chenopodium treatment are alive and can be seen moving when placed in water. Although not dead their movements are very feeble compared with worms obtained without treatment as in the course of a post-mortem examination, so what probably happens is that the worms are sufficiently intoxicated by the drugs to make them loose their hold on the gut and not being able to regain it they are swept out in the faeces. The recognizable worms that were found on the second, third and fourth days are probably worms of this class, that have been loosened from the gut but not killed.

As is usual with any series of hookworm infections examined in Bengal the majority of these persons had mixed infections with *Ancylostoma duodenale* and *Necator americanus* with a marked predominance of the latter species, and a careful analysis of our results from the point of view of the influence of the species on the time of evacuation showed that there was no correlation between these two factors.

Conclusion

The above observations clearly demonstrate that after an efficient anthelmintic treatment the examination of the first stool only, after treatment, gives no indication of the number of worms harboured by the patient, nor of how many cases can be regarded as cured.

Of ureteral causes, the majority of cases show obstruction of the ureter near the bladder followed by dilatation of the ureter, a congenital defect in the wall of the duct, an inflammatory stricture, these are all met with. A congenital obstruction at either end has been explained as due to valvular defects. 'Open' hydronephrosis without actual obstruction is explained as due to a want of co-ordination between the muscular wall of the pelvis and that of the ureter, an achalasia of the pelvi-ureteral junction. A similar want of co-ordination has been described by Kutscherenko at the ureteric orifice of the bladder.

An abnormally high position of the ureter in relation to the pelvis is another congenital defect which causes a valvular obstruction. Such anatomical abnormalities have been discussed by Winsbury White (1925). Stenosis of the pelvi-ureteral junction has been especially studied by Geraghty and Frontz (1918). In all such cases the obstruction was definitely due to inflammatory causes.

Extra-ureteral obstruction as a cause is well known as, for instance, in a case of carcinomatous infiltration from the cervix uteri in our own series. In another case in our series a large hydatid of the lower pole of the kidney had caused pressure below the uretero-pelvic junction. The production of tortuosities, kinks and angulations at the pelvi-ureteral junction have been regarded as primary causes, but the experimental work of Caulk and Fischer (1913) on ureteral ligation has raised the question whether such angulations and kinks are the result of obstruction below. However, the abnormal position of the ureter in its relation to the blood vessels in the neighbourhood may cause a true kinking and resultant obstruction. The kinking due to renal descent in a movable kidney is a well-recognized cause.

The condition was noticed in a girl of eight years who was admitted to the surgical ward of the Government Royapuram Hospital, Madras, on 25th March, 1933. She had an abdominal tumour on the right side. This had become noticeable at the age of four and had gradually increased in size for 4 years. There was nothing in the history to indicate any previous abdominal trouble or injury, though it is probable that the swelling had started much earlier. On clinical examination the tumour was found to be a cystic swelling the size of a small melon occupying the right side of the abdomen extending from the costal margin above to the iliac crest below. It was not movable with respiration and appeared to be fixed to the abdominal wall. The colon resonance extended as a band in front of the tumour so a hydronephrosis was suspected. On cystoscopic examination it was found that no urine was escaping from the ureteral opening on the trigone on the right side, indicating that complete block had occurred in the right ureter. At operation it was found that the swelling was due to a hydronephrosis of the pelvi-renal type involving the right kidney and pelvis. The sac was slightly larger than the size of a foetal head. There was a fascial band causing obstruction near the pelvi-ureteral junction and the ureter below was of normal size. There were two large prominent veins, each of the size of a little finger, passing across the pelvis to the pelvi-renal junction.

These were clamped and the whole tumour was shelled out carefully. The patient made an uneventful recovery.

On examination of the specimen it was found that a greyish band of tissue passed from the pelvis to the ureter, just below the pelvi-ureteral junction, and it had caused an upward pull on the ureter. The structure was a well-defined greyish strand about $2\frac{1}{2}$ inches in length, $\frac{1}{5}$ th inch in width at the pelvic part and $\frac{1}{10}$ th inch wide at its attachment to the ureter. The band was flat and tough, and only about $\frac{1}{20}$ th inch in thickness. It had narrowed down at its attachment to the ureter below, but was flatter and more diffuse at its origin in the pelvis. From the ureter below the uretero-pelvic junction, it stretched upwards and outwards to the pelvis and over the pelvis it passed across the front of the kidney over the true capsule of the kidney (figures 1 and 2). Delicate areolar tissue and compressed masses of fat below this band indicated that it was really a part of Gerota's

Fig. 1.—Photographic drawing (Shennan's method) of the kidney (half natural size), showing the band passing from the capsule of the pelvis to the uretero-pelvic junction with obstruction and kinking at the junction.

renal fascia which had become stretched out owing to the distension of the kidney. This renal fascia, which normally forms a complete investment of the fatty capsule of the kidney, passes usually over the uretero-pelvic junction; but in this case it had become attached to a point on the ureter about half an inch below, and had caused an upward pull on the ureter and a series of kinks just below the uretero-pelvic junction. The ureter below the point of attachment was normal in size and showed no developmental anomaly. Above the point of attachment, the ureter showed a series of well-defined

kinks the whole tube being folded on itself on a vertical plane somewhat after the manner of a flat spiral (figure 2). There were three distinct angulations without any twisting or rotation.

Fig. 2.—Photograph of the kidney (half natural size), showing the band passing from the pelvis to the uretero-pelvic junction. Note that the point of attachment of the band is at the upper part of the ureter. The photo shows it is continued down for a slight extent along the ureter. Note the engorgement of the veins at the junction between the pelvis and the ureter.

A probe could be passed after traction from above downwards through these kinks, right down to the point of attachment of the fascial band where the lumen was distinctly narrowed. The hydronephrosis that resulted was of the pelvi-renal type, but the pelvis was much more distended than the calyces. The empty pelvis was the size of a large orange, while the kidney substance was spread out as a lobulated mass over the calyces; but the whole mass was much larger before the fluid was let out. The superficial veins on the surface of the pelvis and the pelvi-renal junction were all distended (figure 2) indicating that a pyelo-venous backflow had occurred to a considerable extent as a part of the compensatory mechanism. A section through the sac showed that atrophy of the papillae had occurred, but was not extreme. The vascular markings were altered. Pelvic distension was the most marked feature in this case, while renal atrophy was not extreme.

Microscopically, the most conspicuous feature was the dilatation of the collecting tubules. In some areas where atrophy was not very marked the glomeruli were well formed and were in relation to convoluted tubules which showed little of the collapse and atrophy that occurs in advanced hydronephrotic atrophy. These areas

corresponded to the pyramids where the vascular pattern was preserved to some extent. In between, were areas where the renal tissue showed marked atrophy. The distribution of this atrophy was definitely related to the vascular arrangement; where the vessels were stretched from distension, the renal tissue was replaced by a cellular interstitial tissue, resembling that met with in arterio-sclerotic atrophy.

Discussion

Anatomically it is well known that the uretero-pelvic junction is the point at which there is a distinct narrowing of the lumen of the ureter. This is to some extent due to the stretching of the renal fascia over the junction. The fascial band described in this case is very probably a part of this renal fascia which gained an attachment to the ureter, a little below the uretero-pelvic junction. This has caused a distinct narrowing of the lumen and the upward pull of this fascia had caused a kinking of the ureter. No other developmental structure corresponds to the anatomical site of this fascial band. A careful examination, before and during operation, failed to reveal any significant post-natal condition which would explain the formation of this band. The classification of this condition would therefore be that of an anatomical abnormality, rather than an error of development. Abnormal situations of vessels are well-known causes of hydronephrosis. An abnormal attachment of Gerota's fascia would explain this case. The presence of a series of kinks just above the point of attachment of the fascia is a feature of interest. This lends some support to the experimental work of Caulk and Fischer, and to the view that such kinks are generally due to obstruction below. The marked development of the venous collateral system around the pelvis is in keeping with the view of Hinman (1934) of a pyelo-venous backflow as a part of the compensatory mechanism. The clinical finding of a complete 'block' at the time when the patient was examined is also of some significance, in view of the hydronephrotic type of atrophy that had resulted in the kidney. This lends support to the view that the effect of a complete block is not a primary renal atrophy, as originally believed, but that the atrophy is generally of the hydronephrotic type.

The microscopic picture of dilatation of the collecting tubules and ducts of Bellini, with little change in the convoluted tubules in those areas where the vessels pass directly to the cortex, indicates that the hydronephrotic atrophy in the kidney is due to a direct vascular obstruction. The primary effect of an increased intrapelvic pressure in this case is the dilatation of the collecting tubules and ducts of Bellini.

(Continued at foot of next page)

Of ureteral causes, the majority of cases show obstruction of the ureter near the bladder followed by dilatation of the ureter, a congenital defect in the wall of the duct, an inflammatory stricture, these are all met with. A congenital obstruction at either end has been explained as due to valvular defects. 'Open' hydronephrosis without actual obstruction is explained as due to a want of co-ordination between the muscular wall of the pelvis and that of the ureter, an achalasia of the pelvi-ureteral junction. A similar want of co-ordination has been described by Kutscherenko at the ureteric orifice of the bladder.

An abnormally high position of the ureter in relation to the pelvis is another congenital defect which causes a valvular obstruction. Such anatomical abnormalities have been discussed by Winsbury White (1925). Stenosis of the pelvi-ureteral junction has been especially studied by Geraghty and Frontz (1918). In all such cases the obstruction was definitely due to inflammatory causes.

Extra-ureteral obstruction as a cause is well known as, for instance, in a case of carcinomatous infiltration from the cervix uteri in our own series. In another case in our series a large hydatid of the lower pole of the kidney had caused pressure below the uretero-pelvic junction. The production of tortuosities, kinks and angulations at the pelvi-ureteral junction have been regarded as primary causes, but the experimental work of Caulk and Fischer (1913) on ureteral ligation has raised the question whether such angulations and kinks are the result of obstruction below. However, the abnormal position of the ureter in its relation to the blood vessels in the neighbourhood may cause a true kinking and resultant obstruction. The kinking due to renal descent in a movable kidney is a well-recognized cause.

The condition was noticed in a girl of eight years who was admitted to the surgical ward of the Government Royapuram Hospital, Madras, on 25th March, 1933. She had an abdominal tumour on the right side. This had become noticeable at the age of four and had gradually increased in size for 4 years. There was nothing in the history to indicate any previous abdominal trouble or injury, though it is probable that the swelling had started much earlier. On clinical examination the tumour was found to be a cystic swelling the size of a small melon occupying the right side of the abdomen extending from the costal margin above to the iliac crest below. It was not movable with respiration and appeared to be fixed to the abdominal wall. The colon resonance extended as a band in front of the tumour so a hydronephrosis was suspected. On cystoscopic examination it was found that no urine was escaping from the ureteral opening on the trigone on the right side, indicating that complete block had occurred in the right ureter. At operation it was found that the swelling was due to a hydronephrosis of the pelvi-renal type involving the right kidney and pelvis. The sac was slightly larger than the size of a foetal head. There was a fascial band causing obstruction near the pelvi-ureteral junction and the ureter below was of normal size. There were two large prominent veins, each of the size of a little finger, passing across the pelvis to the pelvi-renal junction.

These were clamped and the whole tumour was shelled out carefully. The patient made an uneventful recovery.

On examination of the specimen it was found that a greyish band of tissue passed from the pelvis to the ureter, just below the pelvi-ureteral junction, and it had caused an upward pull on the ureter. The structure was a well-defined greyish strand about $2\frac{1}{2}$ inches in length, $\frac{1}{5}$ th inch in width at the pelvic part and $\frac{1}{10}$ th inch wide at its attachment to the ureter. The band was flat and tough, and only about $\frac{1}{20}$ th inch in thickness. It had narrowed down at its attachment to the ureter below, but was flatter and more diffuse at its origin in the pelvis. From the ureter below the uretero-pelvic junction, it stretched upwards and outwards to the pelvis and over the pelvis it passed across the front of the kidney over the true capsule of the kidney (figures 1 and 2). Delicate areolar tissue and compressed masses of fat below this band indicated that it was really a part of Gerota's

Fig. 1.—Photographic drawing (Shennan's method) of the kidney (half natural size), showing the band passing from the capsule of the pelvis to the uretero-pelvic junction with obstruction and kinking at the junction.

renal fascia which had become stretched out owing to the distension of the kidney. This renal fascia, which normally forms a complete investment of the fatty capsule of the kidney, passes usually over the uretero-pelvic junction; but in this case it had become attached to a point on the ureter about half an inch below, and had caused an upward pull on the ureter and a series of kinks just below the uretero-pelvic junction. The ureter below the point of attachment was normal in size and showed no developmental anomaly. Above the point of attachment, the ureter showed a series of well-defined

chemical composition of which is said to be very similar to that of carbarsone. The effectiveness of this drug against chronic intestinal amœbiasis was carefully tested on a series of cases in the Carmichael Hospital for Tropical Diseases. Most of these patients had *E. histolytica* in the stools in cystic form and suffered from general rather than intestinal symptoms. A few of them were admitted into the hospital for diseases other than amœbiasis, but examination of their stools showed a fair number of vegetative or cystic forms of *E. histolytica*. Amibiarsone was administered by mouth in exactly the same way as carbarsone, 0.25 gramme being given twice daily in gelatine capsules for 10 to 15 consecutive days. The patients were kept on ordinary diet and the bowels were kept open with daily administration of a saline purgative every morning while the drug was being administered. If

there was any evidence of a concomitant bacterial infection a course of autovaccine was also administered. The criterion of cure applied in this series of cases was six or more negative examinations of the stools on different days after cessation of all treatment. It has already been pointed out that this criterion for cure does not indicate that a real cure has been effected, but from experience extending over many years in this country we have found that six negative examinations indicate in the majority of cases a favourable prognosis, if not a definite cure. The difficulty of keeping the patient in the hospital when the acute symptoms are once relieved is very great and it was for this reason that this standard of cure had to be accepted. Whenever possible patients were kept under observation longer, and more examinations were made. The results of the investigation are analysed and given below:—

TABLE

No.	Race, sex, and age	Duration and previous treatment	Laboratory findings before treatment	Treatment	Laboratory findings after treatment	REMARKS
1	H., M., 31	3 years; emetine 12 injections.	Scanty <i>E. h.</i> veg.	Amibiarsone 0.25 gm., b.d., for 10 days.	Negative 6 exams.	Cured.
2	A-I., F., 9	3 months; carbarsone 3 months ago without success.	<i>E. h.</i> (veg. and cyst), <i>E. nana</i> .	I. Amibiarsone 0.125 gm., b.d., for 10 days. II. 6 injections of autovaccine (<i>B. pseudo-carolinus</i> from stool).	Do.	Do.
3	A-I., M., 18	6 months ..	<i>E. h.</i> (veg. and cyst), <i>E. nana</i> .	Amibiarsone 0.25 gm., b.d., for 15 days.	Negative 7 exams.	Do.
4	H., M., 29	Scanty <i>E. h.</i> veg., hookworm ova, <i>Streptococcus faecalis</i> , <i>B. asiaticus</i> .	Amibiarsone 0.25 gm., b.d., for 7 days.	Left on risk bond on the 7th day of treatment. (Indeterminate). Cured.
5	H., M., 50	1 year ..	Scanty <i>E. h.</i> veg., hookworm ova.	Amibiarsone 0.25 gm., b.d., for 15 days.	Negative 7 exams.	Do.
6	H., M., 28	2 years ..	Scanty <i>E. h.</i> veg. and cyst, <i>I. butschlii</i> cysts, <i>E. nana</i> veg. and cysts, <i>Streptococcus faecalis</i> .	Amibiarsone 0.25 gm., b.d., for 10 days.	Negative 6 exams.	Do.
7	H., M., 30	Present attack 2 years. Dysentery 12 years ago. Emetine 21 injections.	<i>E. h.</i> veg., cellular exudates.	Amibiarsone 0.25 gm., b.d., for 20 days.	<i>E. h.</i> cysts, C-L crystals.	Failed.
8	M., M., 38	Originally admitted for diabetes.	<i>E. h.</i> cysts, <i>E. nana</i> cysts, hookworm ova, malignant tertian malaria.	Amibiarsone 0.25 gm., b.d., for 10 days.	Negative 6 exams.	Cured.
9	H., F., 16	4 months ..	Very scanty <i>E. h.</i> veg., ascaris and trichuris ova.	Do.	Do.	Do.
10	I-Ch., F., 45	Originally admitted for filariasis. Dysentery in childhood.	<i>E. h.</i> veg. and cyst, blastocystis, trichuris ova.	Amibiarsone 0.25 gm., b.d., for 15 days.	Negative 5 exams.	Indeterminate.

TABLE—contd.

No.	Race, sex, and age	Duration and previous treatment	Laboratory findings before treatment	Treatment	Laboratory findings after treatment	REMARKS
11	M., M., 37	Admitted originally for lupus erythematosus.	Scanty <i>E. h.</i> cysts, hookworm ova.	Amibiarson 0.25 gm., b.d., for 15 days.	Negative 6 exams.	Cured (negative from the 8th day of treatment).
12	M., F., 36	Originally admitted for chyluria.	Scanty <i>E. h.</i> cysts	Amibiarson 0.25 gm., b.d., for 10 days.	Negative 6 exams.	Cured.
13	H., M., 12	Admitted originally for asthma.	<i>E. h.</i> cysts, giardia cysts, <i>I. butschlii</i> , hookworm ova, ascaris ova, trichuris ova.	I. Amibiarson 0.25 gm., b.d., for 10 days. II. Autovaccine (from sputum) 6 injections.	Negative 9 exams.	Cured (negative from the 8th day).
14	H., M., 16	1 year ..	<i>E. h.</i> cysts, giardia cysts, hookworm ova.	Amibiarson 0.25 gm., b.d., for 10 days.	Negative 6 exams.	Cured (negative from the 8th day of treatment).
15	H., F., 13	2 years ..	<i>E. h.</i> cysts, <i>I. butschlii</i> , <i>E. nana</i> , trichuris ova, tænia ova.	Do.	Do.	Cured (negative from the 8th day).
16	H., F., 20	Originally admitted for anæmia, suffered from dysentery 4 years ago.	<i>E. h.</i> cysts, <i>B. lactis ærogenes</i> .	Do.	Do.	Cured.
17	H., F., 39	22 years ..	<i>E. h.</i> cysts, <i>B. pseudocarinatus</i> , hookworm ova, <i>A. metalcaligenes</i> .	I. Amibiarson 0.25 gm., b.d., for 10 days. II. 6 injections of autovaccine (<i>B. pseudocarinatus</i>).	I. Negative 6 exams. II. Giardia cysts.	Do.
18	H., M., 30	6 months for the present; suffered from amebic dysentery 12 years ago.	<i>E. h.</i> cysts, hookworm ova.	Amibiarson 0.25 gm., b.d., for 10 days.	Negative 6 exams.	Do.
19	H., M., 35	7 years ..	<i>E. h.</i> cysts, hookworm ova, giardia cysts.	Do.	Do.	Do.
20	M., F., 16	Originally admitted for contracture of hand (hysteric).	<i>E. h.</i> cysts, hookworm and trichuris ova, <i>B. jæcalis alkaligenes</i> .	Do.	Do.	Do.
21	H., F., 11	1 year ..	<i>E. h.</i> (veg.), giardia cysts, <i>B. jæcalis alkaligenes</i> , <i>B. pyocyaneus</i> , <i>B. paratyphosus</i> (?).	Amibiarson 0.25 gm., b.d., for 15 days.	Negative 7 exams.	Do.
22	M., M., 55	3 years, dysentery 15 years ago.	<i>E. h.</i> (veg.)	Amibiarson 0.25 gm., b.d., for 10 days.	Negative 6 exams.	Do.
23	H., M., 29	12 years emetine. Cabarsone (Lilly) Gavano Autovaccine Kurchi	<i>E. h.</i> cysts, <i>B. pyocyaneus</i> .	I. Amibiarson 0.25 gm., b.d., for 10 days. II. Amibiarson 0.25 gm., b.d., for 5 days after an interval of 5 days.	Degenerated <i>E. h.</i> cysts. Negative 6 exams.	Do.
24	H., M., 32	6 months ..	<i>E. h.</i> cysts, hookworm ova.	Amibiarson 0.25 gm., b.d., for 10 days.	Do.	Do.
25	M., M., 21	Originally admitted for filariasis.	<i>E. h.</i> cysts, hookworm and trichuris ova, <i>B. lactis ærogenes</i> , urine culture staphylococci.	Amibiarson 0.25 gm., b.d., for 15 days.	Negative 7 exams.	Do.

TABLE—cont'd.

No.	Race, sex, and age	Duration and previous treatment	Laboratory findings before treatment	Treatment	Laboratory findings after treatment	REMARKS
26	H., F., 45	Originally admitted for dermatitis.	<i>E. h.</i> cysts, <i>B. pseudo-carolinus</i> , <i>B. lactis aerogenes</i> .	Amibiarson 0.25 gm., b.d., for 15 days.	Negative 4 exams.	Indeterminate.
27	E., F., 9	1 month ..	Scanty <i>E. h.</i> (veg.), <i>B. pseudo-carolinus</i> .	I. Amibiarson 0.125 gm., b.d., for 10 days. II. 6 injections of autovaccine (<i>B. pseudo-carolinus</i>).	Do.	Do.
28	H., M., 20	6 months ..	<i>E. h.</i> (veg.) + +, C.-L. crystals + +, atypical flexner.	I. Amibiarson 0.25 gm., b.d., for 10 days. II. 6 injections of autovaccine.	I. Scanty <i>E. h.</i> (veg.), C.-L. crystals. II. After the course of vaccine <i>E. h.</i> (veg.), C.-L. crystals.	Failed.
29	H., M., 30	Originally admitted for malaria.	<i>E. h.</i> (veg. and cyst), <i>E. nana</i> (veg. and cyst), blastocystis + +, hookworm and ascaris ova and strongyloides larvæ.	Amibiarson 0.25 gm., b.d., for 10 days.		Pt. left on the 6th day of treatment. Indeterminate.
30	E., M., 32	Since childhood; worse recently.	<i>E. h.</i> (veg. and cyst) +, <i>E. nana</i> (veg. and cyst) +, blastocystis +, <i>B. faecalis alkali-genes</i> .	I. Amibiarson 0.25 gm., b.d., for 10 days. II. 6 injections of autovaccine.	Negative 4 exams.	Indeterminate
31	M., F., 38	5 years ..	<i>E. h.</i> (veg.), scanty <i>E. nana</i> (veg. and cyst), + +.	Amibiarson 0.25 gm., b.d., for 10 days.	<i>E. h.</i> (veg.) + C.-L. crystals +	Failed.
32	A.-I., M., 3	<i>E. h.</i> (veg. and cyst) +.	Do.	Negative 2 exams.	Indeterminate.
33	Jew, F., 46	1 month for the present, dysentery 5 years ago.	<i>E. h.</i> (veg.) +	Do.	Negative 6 exams.	Cured.
34	H., M., 7	Originally admitted for hæmophilia.	Scanty <i>E. h.</i> (veg.), oxyuris and trichuris ova.	Do.	Negative 7 exams.	Do.
35	A.-I., M., 21	Originally admitted for malaria.	<i>E. h.</i> (veg.) +.	Do.	Negative 4 exams.	Indeterminate.
36	M., M., 25	1 year ..	Scanty <i>E. h.</i> (veg.), hookworm ova, <i>B. pseudo-asiaticus</i> .	I. Amibiarson 0.25 gm., b.d., for 10 days. II. Amibiarson 0.25 gm., b.d., for 5 days.	Scanty <i>E. h.</i> veg. Negative 3 exams.	I. Failed. II. Indeterminate.
37	H., M., 24	Originally admitted for elephantiasis leg. Dysentery 12 years back.	Scanty <i>E. h.</i> (veg. and cyst), hookworm ova.	Amibiarson 0.25 gm., b.d., for 10 days.	Negative 6 exams.	Cured.
38	M., M., 40	5 years emetine	<i>E. h.</i> (veg.) + +, cellular exudates + + +.	I. Amibiarson 0.25 gm., b.d., for 10 days. II. Amibiarson 0.25 gm., b.d., for 5 days more.	I. Scanty <i>E. h.</i> (veg.). II. Negative 2 exams.	Failed. Indeterminate.

A Mirror of Hospital Practice

A CASE OF INTESTINAL OBSTRUCTION CAUSED BY EXTRA-UTERINE PREGNANCY

By S. R. GORE, L.M. & S.

Honorary Surgeon, The Hubli Co-operative Hospital Society, Hubli

G. D., AGED 28, was admitted to the Co-operative Hospital, Hubli, in the afternoon of 29th January, 1935, for intestinal obstruction.

Her condition was grave; thready rapid pulse, cold perspiration, anxious look, frequent vomiting of large quantities of liquid faecal matter, and distended abdomen were the marked symptoms. Patient was given an enema before admission but as it had no effect she was brought to hospital.

On examination the lower portion of the abdomen up to the umbilicus was dull to percussion and there was tympanites above. There was a bloody discharge from the vagina. The patient was examined about ten days previously in the outpatient department for pain in the abdomen, amenorrhœa of three months' duration and tumour. She gave a history of irregular and profuse menstruation for a couple of months previous to the amenorrhœa and the tumour was noticed during this period. It was a right-sided tumour, its feel was irregular and hard and it seemed fixed. She had had no children before this. She was examined *per vaginam* by my colleague, Miss Engineer, who reported that the os uteri was soft and the breasts were areolated and there was milk in them. She diagnosed pregnancy but said the feel was queer. She could not hear either uterine souffle or foetal heart sounds. I was not allowed to examine *per vaginam* and a diagnosis of pregnancy of three months with a fibroid of the broad ligament was made by me as the period of three months' amenorrhœa was insufficient to explain the size of the tumour and no foetal heart sounds were heard. I took the tumour which was one-sided to be a fibroid. Patient was advised to stay in the hospital and that an operation was necessary. She refused to stay and went back to her village. With this history in mind, I thought that the obstruction was due to the impaction of the tumour. I had previously seen a case of a big pedunculated fibroid jammed in the pelvis causing obstruction and gangrene of about two feet of the ilium. As the condition of the patient was extremely grave I thought that an operation could not be undertaken unless the pulse improved. I therefore directed the house surgeon to wash out her stomach every two hours during the night and give her glucose and saline intravenously.

The next morning, though the condition was still serious, I could at least feel the pulse and there was no cold perspiration. I decided to do an enterostomy to relieve the condition and then tackle the tumour at a later date if she improved. An incision of one inch was thus made below the umbilicus in the midline, under local anaesthesia. On opening the peritoneum a foul-smelling reddish discharge escaped but no loop of the gut protruded. The finger was therefore introduced and a soft placenta-like mass felt; on going further in by the side of this, I felt the limbs of the foetus. The incision was then enlarged downwards after injecting novocain and the foetus removed, the cord was black and was easily torn away while extracting the foetus. The placenta which was attached to the anterior abdominal wall and loops of the intestine was almost detached of itself and was easily removed without any bleeding. After mopping away the fluid in the cavity a gauze drain was introduced and two through-and-through stitches were put in the upper end of the wound. The pressure of the impacted head of the foetus being removed it was thought unnecessary and inadvisable to disturb the intestines and even the

uterus to ascertain which tube was responsible for the pregnancy. The uterus was retroverted and was being pushed down by the foetal head causing pressure on the pelvic colon and thus obstructing it.

In the ward 1 c.cm. of pituitrin was injected and a flatus tube inserted. She had neither passed flatus nor stool till midnight but the vomiting had stopped. She was restless so the stomach was again washed with bicarbonate of soda solution in the evening, and intravenous saline with glucose was given at midnight with 2 c.cm. myosin intramuscularly. On the 31st, flatus was being passed through the tube and in the evening she had a copious motion. This was followed by diarrhœa for a couple of days. She had lung complications but ultimately recovered and was discharged cured on 13th March, 1935.

A CASE OF HYSTERICAL HICCOUGH*

By A. C. ROY

Charitable Dispensary, Balagaria, Midnapore

A FEW months ago a Hindu male, aged 35 years, came to the dispensary complaining that for the last two years he had been involuntarily making a retching noise.

Previous history.—His relatives said that eight or nine years ago he was insane, insisting on removing his clothes, but he had ceased behaving in this manner for a long time now. About two years ago the man became unconscious and a little blood trickled out of his mouth. He quickly regained consciousness following the application of cold water to his head. Shortly after this he commenced to make the noise complained of and this has continued ever since.

Examination.—The patient stands and walks with the head and upper part of the body slightly tilted backwards; this only began after the attack of unconsciousness. No other abnormality was found and there is no defect in his talking voice.

The man makes a sound somewhat like that of retching five or six times a minute except when talking or when he is asleep. He holds his mouth half open and when ordered to close it and he breathes through his nose the sound continues. He was quite unable to stop making the noise by exercise of his will.

A mixture containing valerian, belladonna and arsenic was prescribed and the intervals between the noises gradually increased and finally they ceased altogether after he had been taking the medicine regularly for three weeks. One month later the man began again to make the noises but a repetition of the mixture rapidly cured him.

The history of mental instability, the absence of any apparent cause, and the nature of the cure suggest that the case is one of pure hysteria.

A CASE OF ANOPHTHALMOS

By INDRASINH, L.C.P. & S. (Bom.)

Central Hospital, Alirajpur, C. I.

A BABY aged 5½ months, resident of Nanpur in Alirajpur State, was brought to the outpatient department of the Central Hospital on the 31st January, 1935, the mother complaining the child was unable to see. I tried to separate the lids, but was unable to expose the eyeballs, as the former were adherent in the greater part of their length except a small portion in the centre.

The baby was put under ether anaesthesia and the eyeballs were found to be simple cystic structures overlapped with conjunctiva. The condition was bilateral and there were no other anomalies such as harelip. The orbit was smaller than normal.

JUNE

ASCARIS INFECTION AND THE BORE-HOLE LATRINE

NEARLY five years ago we discussed in an editorial the problem of infection with *Ascaris lumbricoides*. At that time we drew attention to the need for proper disposal of night-soil as well as treatment of infected persons if this widespread infection were to be controlled.

Since that time research has shown that treatment alone is quite ineffective, and that if an infected community is treated without improvement in sanitation the infection rate returns to its original degree and intensity in less than three months. In this respect the ascaris problem differs from the hookworm problem because thorough and periodical treatments for the latter infection have been shown to reduce the community rate and even more markedly the individual intensity of infection of a heavily infected community, and that they do not rise to their original level for a much longer time.

It is generally agreed that ascaris infection is fairly rapidly lost, or at all events considerably reduced, if reinfection is prevented. This fact combined with the knowledge that treatment alone is useless emphasizes the necessity of the proper disposal of infected stools as being the only solution of this problem, in the present state of our knowledge.

Recently Clayton Lane has collected one or two records which indicate the possibility that imperfect sanitary measures actually lead to an increase in infection rate with ascaris. How this occurs is not yet clear, but it is a disturbing thought and indicates that the problem is not quite as simple as at first sight it appears. The two principal instances quoted by Lane are one of his own finding in the Darjeeling district some years ago and the other in some small villages in Panama. In the Darjeeling instance the most heavily infected tea garden coolies were found in the only garden where any attempt at installation of latrines existed, these were only seats overhanging a deep ravine and the stools just fell down the steep hillside where they were left to putrefy. In Panama pit latrines were instituted at individual houses in the villages. Later examination showed that they were not being used by all the inmates of the houses, and that the children were the chief delinquents. Clayton Lane suggests that the ascaris eggs are air-borne and enter the houses to contaminate the food, but this suggestion seems of doubtful accuracy, in Panama—at all events, for there the rise in infection rate

occurred at the height of the wet season, which is exceptionally heavy and continuous, so that it is difficult to imagine such relatively large and rounded bodies as ascaris eggs being carried by air at such a time. But whatever the cause of this increase in infection after installation of latrines the faeces in the Darjeeling example were freely exposed and in Panama they were in open latrines of the pit type though covered by buildings and seats.

For the past few years bore-hole latrines have been widely advocated principally by sanitarians of the Rockefeller Foundation and they are now in use to a great extent in the Malay States and the Dutch Indies, but they have not made much headway in India although they are used to some extent in Madras Presidency and one or two other areas. If air-carriage of eggs after the installation of inadequate latrines is the correct explanation of the failure to reduce or to even cause an increase in ascaris infection, the bore-hole latrine should not be open to this objection, especially if bored deep enough to enter the sub-soil water, a condition that will apply in the plains of Bengal and Assam.

It has been shown over and over again that partial use of latrines by a community has practically no effect in reducing intestinal worm infections of any kind, and that if any benefit is to be derived from their installation the whole population (especially the children who are given to defæcating close to the houses) must make use of them. Bore-hole latrines have the great advantages of cheapness, and speed and ease of construction so that they can be supplied quickly to all the houses of a community such as a coolie line or small village. Each house being furnished with such a convenience means that it will be near the dwelling, and this proximity should go a long way towards encouraging their regular use by the inhabitants as will also the privacy thus afforded, compared to that of a large central public latrine. Fouling of the latrine and its surroundings seems to us much less likely to occur in these small private latrines than in the large public type where this is a very real disadvantage. For one reason, persons are always more inclined to take proper care of their own property than that of the public, and another reason is that if fouling does occur it will be much easier to discover the culprit and deal appropriately with him among the members of a single family.

If bore-hole latrines reach the sub-soil water and not too many individuals use each one complete liquefaction of faeces will occur and the liquefied matter will percolate through the soil and so become completely lost. In some countries where night-soil is a source of manure for vegetables and cereal crops the establishment of latrines from which the faecal material cannot be recovered is strongly objected to by the

agriculturists because an important source of income is lost to them. In India this difficulty at least is absent because night-soil is practically not used at all as manure.

It must be remembered that from the evolutionary standpoint the sanitary disposal of faeces is a very recently acquired habit of the human race, and is the direct result of our discoveries in the epidemiology and transmission of many diseases and the education of the public therein. Amongst the highly educated, cleanliness in this respect is now almost instinctive, but it is surprising how careless and insanitary many of the less-educated are even among the most civilized races. Accordingly it should be remembered that the sudden introduction of latrines to a primitive people is a most severe disturbance of the routine that has existed from the beginning of the race, and that a certain amount of opposition will always be met with, and difficulty will be experienced in finding a few members of the community sufficiently adventurous to begin this entirely unheard of habit of using latrines, and thus to make a start in the education of the whole population.

If the first latrines are of a public character and for the general use of the community, as they often are, they will be objected to on several grounds; firstly the building itself will probably be of a type to which the native is unaccustomed so he will hesitate to enter such

a strange place, secondly it is a deeply ingrained instinct to seek privacy for the act of defæcation (this can often be observed even among the lower animals) consequently the people are unwilling to throw aside the habit of generations of retiring secretly to the bush for this purpose and instead of this to parade publicly through the village and enter the latrine in full view of many of their companions, and lastly public latrines are very often allowed to get into such a filthy condition and are so offensive that objection to their use is not at all unreasonable.

Bore-hole latrines, on the other hand, are small, they can be situated close to the houses and can be covered with simple bamboo or grass shelters, a type of architecture to which the native is accustomed, and so he will have no fear in entering them, they are quite private and on account of the comparatively few persons who use each one of them the surrounding surface is less likely to become fouled and offensive.

On account of the advantages we have detailed this type of latrine appeals to us as the type most likely to be successfully used by primitive peoples. Accordingly they should be the most efficient in controlling the scourge of intestinal helminthic infections, especially that of *ascaris*, which is of much more importance among rural communities in the tropics and sub-tropics than is generally recognized.

Commentaries

STUDY OF THE CHOLERA VIBRIO

THE EPIDEMIC AND ENDEMIC TYPES OF CHOLERA VIBRIOS

By D. DOORENBOS, M.D.

*Director of the Quarantine Laboratory of Egypt,
Alexandria*

IN this brochure, Dr. Doorenbos, by dividing cholera vibrios into two definite types, viz, the *epidemic* and the *endemic*, attempts to reconcile and explain the many diverse and puzzling observations and findings that have been made at different times, and in different countries and circumstances, regarding the cholera vibrio. While most will question the justifiability of this division in the present state of our knowledge, nevertheless the brochure contains much interesting matter both of fact and speculation. Taking certain facts first, Dr. Doorenbos records that agglutination by a high-titre serum as a fundamental diagnostic property of a 'true' cholera vibrio was first laid down by Kolle and Gotshlich in 1903. This choice by Kolle of an epidemic cholera vibrio as the only true and veritable antigen was arbitrary and a great deal of the present confusion is due to this choice. Kolle and Gotshlich in Egypt, however, themselves found many discrepancies in this agglutination reaction, but attributed the irregularities to faults in plating technique and to contaminations. In 1905 Gotshlich at El Tor found in returning pilgrims the types of vibrios now associated with the name 'El Tor'. These were

agglutinable and hæmolytic, and were not associated with cholera cases, nor was there any cholera in the Hedjaz that year. (Doorenbos rightly distinguishes between the hæmo-digestion found in solid media, and the hæmolysis in liquid media. Much confusion has arisen in the literature by misstatements in this respect.) Their agglutinability, according to accepted opinion, placed these El Tor vibrios in the class of true cholera vibrios, but their hæmolytic property and their lack of any association with cholera cases were at variance with this view. The discovery, notably by Pasricha, that true cholera in an endemic area was associated with non-agglutinable vibrios especially at the beginning of the epidemic season was another reflection on the property of agglutination being essential to virulence. In epidemics outside endemic areas, however, the agglutinable vibrio seems to predominate. The finding of non-agglutinable vibrios in large percentages of healthy people in endemic areas in Bengal by Tomb and Maitra, and B. B. Brahmachari, and the comparative rarity of carriers of agglutinable vibrios in such areas, were facts difficult to appraise. The sanitary authorities in Syria in 1931 found large numbers of healthy carriers of agglutinable vibrios coming from Iraq which at the time was infected with epidemic cholera, but they found similar carriers also from areas which were quite free of infection. These agglutinable vibrios occurred also amongst inoculated persons. What is the significance of all these observations? What parts do agglutinable and non-agglutinable vibrios play in the occurrence of cholera; what is the part played by the so-called healthy

carriers of the non-agglutinable and agglutinable vibrios? What is the explanation of endemicity, and how should we account for the different behaviour of vibrios in endemic and epidemic areas? These and many other related questions need solution and most workers agree that speculation at the present stage is not justified, but that further investigation and observation, at first in an endemic area, are necessary. This is the view taken by the Indian Research Fund Association which has financed investigations into the problems of endemicity at the School of Tropical Medicine and the All-India Institute of Hygiene and Public Health; and in which the Central Research Institute of Kasauli and the Pasteur Institute of Assam are also co-operating.

Dr. Doorenbos, however, thinks that speculation is justified and has postulated certain ideas. If we understand him correctly he would envisage the various stages in the carriage of cholera somewhat as follows:—

(1) Taking the height of an epidemic (either in an endemic or non-endemic area) as a starting point, ultra-pure vibrios are alone found. These vibrios are agglutinable, they completely absorb agglutinins and give a positive Pfeiffer reaction; they produce no hæmolytic in a liquid medium, and are lysable by cholera bacteriophage. They are what Doorenbos calls the *epidemic* type of vibrios. They breed unaltered from culture to culture. In epidemics in non-endemic areas, the ultra-pure type predominates throughout. They are usually phage free.

(2) As the epidemic wanes, these ultra-pure vibrios are replaced by modified types, often non-agglutinable, and variable also in their reaction to blood medium. These vibrios are probably symbiotic with phage, and their characters on subculture often vary from culture to culture. They are derived from the ultra-pure types probably by phage action and are the *endemic* type of vibrio. In an endemic area these types persist (probably both in human beings and in water) in inter-epidemic periods. In a non-endemic area there is a complete disappearance of all types, and reintroduction is necessary for another epidemic to occur.

(3) At the resumption of an epidemic in an endemic area, modified types appear at first, being replaced by ultra-pure epidemic types at the height of the epidemic; and so the cycle is completed.

The gap in knowledge lies between the endemic type of vibrio which does not cause cholera and the same organism when, and if, it starts to cause cases of cholera. It is our ignorance in this matter that makes unjustifiable the assumption of applying the two terms 'epidemic' and 'endemic' to the organisms.

Doorenbos distinguishes between cholera-genic capacity and virulence. By the former term is meant the capability of producing cholera-like symptoms either in man or in the rabbit (in the latter by enterotrophy in association with other intestinal organisms). By 'virulence', however, he means the property of being able to initiate the entity of human cholera and to carry it on from case to case. In this sense the authentic or *epidemic* vibrio is both cholera-genic and virulent. The *endemic* type is cholera-genic only and not virulent. It can produce sporadic cases of cholera or cholera-like symptoms, but cannot start an epidemic. The endemic type according to Doorenbos is transmutable in nature in endemic areas at least into the epidemic type, but the factors operating in this transmutation are unknown. The Hedjaz, though not an endemic area, has within it the properties of converting the endemic into the epidemic type. These are the main points of Dr. Doorenbos' thesis as presented in his brochure. These ideas are not new; they are practically those postulated by Tomb and Maitra in 1930. In addition there are in the brochure interesting data about methods of isolating the vibrios from large numbers of individuals at one time, and a description of the El Tor quarantine station. Though we may not agree with Dr. Doorenbos' speculations or

rather that we consider they are not justified, with our present knowledge, nevertheless he has written an interesting booklet which all workers on cholera will read with interest and pleasure.

(Dr. Doorenbos' communication, we note, was considered by the Cholera Commission at the October 1934 meeting of the Office International. The Commission record their opinion as follows. Referring to the terms *typus epidemic* and *typus endemic*, the Commission state 'It appears that Dr. Doorenbos is creating a new term for what are probably cholera variants, and the Commission considers that the nomenclature suggested is misleading. The statement that these forms are essentially reversible is one which the Commission does not consider to have been proved. During a recent pilgrimage the examinations of stools at El Tor on the outward journey did not result in the discovery of any carriers, but on the return from the Hedjaz a proportion showed vibrios. From this Dr. Doorenbos concludes that a specific source of infection must exist in the Hedjaz. The delegate from Dutch East Indies has suggested the advisability of carrying out examinations of pilgrims at ports of departure in his country and also in British India to determine whether they carry vibrios which are later picked up by the pilgrims from Egypt. It might be considered whether this could be done at Bombay'.)

THE IMMUNOLOGICAL PROBLEMS OF THE TYPHUS FEVER GROUP AS RAISED BY A SPORADIC CASE OF TYPHUS (VECTOR UNKNOWN) FROM HAMIRPUR IN THE PLAINS OF INDIA WITH A NOTE ON THE HISTORY OF TICK TYPHUS IN INDIA

By H. STOTT, M.D., F.R.C.P., D.P.H.

LIEUTENANT-COLONEL, I.M.S.

Professor of Pathology, King George's Medical College, Lucknow, and Physician to the Hospital

OF the many brilliant services rendered to tropical medicine in India by Major-General Sir John Megaw, K.C.I.E., I.M.S., one time Professor of Pathology and Principal of King George's Medical College, Lucknow, and Physician to the Hospital, perhaps none have become more important than his publication of the first clearly recognized case of tick typhus which he himself contracted in 1916 near Bhim Tal in the Himalayas (Megaw, 1917 and 1921). This publication was followed by his diagnosis of the second case of tick typhus recognized in India which was also investigated at this Medical College, and by his subsequent writings on the typhus fever group (Megaw, 1921, 1924 and 1925). It is therefore not unfitting that the third case of tick typhus, diagnosed at King George's Medical College, should be reported, and the more so since the investigation of this third case raises problems of great immunological interest, extending beyond the realm of tick typhus, to the whole typhus and rickettsia group and, even, into the more obscure problems of immunology itself. These problems which at present can be only lightly hinted at are best approached by a consideration of:

I. The history of the recognition and diagnosis of tick typhus in India.

II. The clinical history of the third tick typhus case at King George's Medical College.

III. The immune responses demonstrated in this third case and by the typhus fever group as a whole.

This third case is described here as tick typhus, but in fact the vector was unrecognized. A more accurate scientific diagnosis would be a case of sporadic typhus due to an unknown vector.

I. THE HISTORY OF THE RECOGNITION AND DIAGNOSIS OF TICK TYPHUS IN INDIA

The history of the recognition and diagnosis of tick typhus in India is a history of three well-defined steps. These three steps are instructive and well worthy of recollection. The first step was McKechnie's recognition on clinical data that the endemic continued fever of Bhim Tal was mainly a subvirulent typhus infection, which however had not the usual typhus epidemiology, but was sporadic and unassociated with lousy conditions. The second step was Megaw's aetiological observation that a case of Bhim Tal fever followed a tick bite—and that its sporadic nature was due to the life habits of that insect, viz, a chance bite of an infected tick in the jungle wilds. Further, Megaw stressed the similarity of Indian tick typhus with the spotted fever of the Rocky Mountains which was known to be conveyed by tick bites. The third step was the curious serological findings in typhus serum which came to be recognized as obscuring the diagnosis and which are more fully noted below.

Step 1.—McKechnie's clinical recognition that the mild endemic, continued fever of some 15 days' duration of Bhim Tal, though unassociated with lice, was due to mild typhus and not to mild typhoid infection.

For long it had been known that a continued fever of some ten to fifteen days was endemic in the small hill stations of Bhim Tal and the adjoining Sat Tal which were located at a height of 4,500 feet above sea level near Naini Tal, the summer headquarters of the Government of the United Provinces. European visitors to these places readily contracted this fever which was generally believed to be due to typhoid or to paratyphoid infection. And this belief was supported by a number of positive Widal reactions. During four months in 1913, Major (now Lieutenant-Colonel) McKechnie, I.M.S., investigated these endemic cases starting with the preconceived popular idea that he was dealing with 'enterica' which diagnosis a certain number of positive Widal reactions seemed to support. Blood cultures however were completely negative. Once Assistant Surgeon Hardy, I.M.B., suggested a diagnosis of typhus in the case of a European lady at Sat Tal, but Major McKechnie, scouted the idea 'on the epidemiological grounds that typhus was a disease of city slums, of filth, of overcrowding and of bad ventilation and not at all the kind of disease that one would expect to find in a lady living in a cottage in the Sat Tal jungle'. And Assistant Surgeon Hardy revised the diagnosis to the more acceptable one of paratyphoid A. Major McKechnie's soliloquy on this incident is worth quoting in full. 'Thus does authority browbeat us all, and, obsessed as we are by *obiter dicta* and dogmas, which, though no doubt applicable to the circumstances under which they arose, are not necessarily of universal application, the tender shoot of truth attempting to rear its head is blighted by the cold wind of tradition'. But owing to the constant negative blood cultures, the irregular Widal results, the short average duration of the fever (thirteen days), and the wide distribution of the copious rash, Major McKechnie was gradually forced to the conclusion that in the majority of cases he was not dealing with even mild typhoid. He further noted that 'there were only typhus fever, Brill's disease, and the spotted fever of the Rocky Mountains amongst the continued

possible epidemic fevers which failed to yield positive blood cultures'. After a thorough investigation of a further case, in which the Widal reactions were fortunately found negative, Major McKechnie wrote 'I simply had to revise my notion and then I found that the only thing against my thinking of typhus for other cases which had occurred was my obsession as to the epidemiology. If some of the cases were typhus then it must be the obsession that was wrong'. McKechnie concluded that typhus fever, usually subvirulent, was endemic in this area, and was the chief danger to the health of Europeans there. Major McKechnie's most valuable contribution to the study of typhus group in India was this recognition of a subvirulent, endemic, localized form, associated with jungle life, and in which filth and overcrowding and famine played no part. As Megaw states it is a matter of great regret that Major McKechnie merely submitted his report in the official manner to Government and did not publish so instructive and human a document. We, however, owe, much to Megaw (1921) for his review of it from which the above extracts are made.

Step 2.—The next historical step forward was the fortunate circumstance (fortunate that is for Tropical Medicine in India) that Megaw himself contracted the disease following a tick bite near Bhim Tal and thus had his interest aroused in it. His great contribution was the recognition of the fact (and his teaching and publication thereof) that there existed in various parts of the world (e.g., in the Rocky Mountains of America) a mild variety of typhus fever which occurred in endemic rather than in epidemic form and was unassociated with filth, overcrowding and poverty, but rather with open-air life in the jungle wilds and thus was conveyed, probably, by ticks and not by lice. Megaw formed 'the strong opinion' that the infection was one primarily affecting animals of the jungle (rodents) and was conveyed to man by a tick. Megaw also stated his belief that the disease was probably widely distributed in the hills and plains of India and also in other parts of the world but that the disease remains unrecognized because of its superficial resemblance to typhoid fever. On the nosological side Megaw's very practical classification of the typhus fever group into (1) Louse, (2) Tick and (3) Mite typhus (the latter a disease of recently flooded places) and into (4) Typhus of Unknown Vector, further clarified the position whilst his writings, teaching and addresses widely diffused this new knowledge. Megaw's first two cases both at King George's Medical College are briefly recorded in the appendix. Further cases were reported from Nagpur and Saugor in Central India, from Bangalore in Mysore, from Angul in Orissa, from Dacca in Bengal, from Akyab in Burma, from South Africa (McNeight), from Australia and from Nigeria. The experience of the last few years seems to indicate the wide distribution of this disease.

Step 3.—The third step is the recognition on the serological side of the widespread prevalence of different antibodies in typhus serum during and towards the end of fever (e.g., typhoid and proteus agglutinins, syphilitic amboceptor and opsonin). In the past this widespread prevalence has led to confusion (1) in the serological diagnosis of typhus fever from the typhoid group, (2) in attempts to subdivide the typhus group according to the agglutination response of typhus serum to various strains of proteus bacillus and (3) in the support of claims put forward for various organisms to be the real bacterial cause of typhus since such organisms agglutinated with apparently homologous antibodies in the typhus patient's serum. The present paper is mainly directed to the varied heterologous antibodies so often present in typhus serum.

II. CLINICAL HISTORY OF THE THIRD TICK TYPHUS CASE AT KING GEORGE'S MEDICAL COLLEGE

The Rev. S., a pure-born American missionary, 28 years of age, was admitted into my ward in King

I. The history of the recognition and diagnosis of tick typhus in India. The

III. The immune responses demonstrated

third case and by the typhus fever general condition. This third case is described here. The pains and in fact the vector was unrecognized as disappearing first scientific diagnosis would be a thigh with the gradual due to an unknown vector. normal on this the twenty-every. The spleen which had

the history of the breadth was not receding. By the 14th the agglutinins which had reached 1/250

descent for history to 1/2,500 on the 10th. November, the patient had been convalescent for a week. The rash had disappeared from the face, arms and arms and was rapidly fading from the

On the 28th November the patient was discharged from hospital, completely convalescent. The rash staining was still obvious on the feet, round the ankles and up to the knees. Each stain was lean ham and coppery in appearance and from about one-quarter to one-half inch in diameter. The staining could be clearly made out on the palms and soles. Desquamation was present in these areas but not on the body. The rash had disappeared as follows, from the chest, body, face, hands, feet, i.e., in the same order as of appearance. On the 1st December, staining was still present on the palms and soles, slightly on the forearms and to a somewhat greater extent on the legs.

Diagnosis.—The clinical diagnosis of tick typhus in this case was clear. The onset occurred (1) in an American Missionary non-immune to the locality. (2), who had been camping in tents in contact with village and open jungle life for 15 days previous to the onset of his infection (i.e., the common incubation period of 7 to 12 days lay within the exposure period). The second case of tick typhus reported in the appendix was that of a forest officer working in the jungles of Hamirpur, who contracted his infection in the same month (October). An endemic centre may therefore be presumed in this area though no definite evidence is at present available. (3) His camps were pitched in an area known to be more tick-infested than most other areas of the United Provinces and in an area where tick fever in horses and dogs (though the infecting agent is believed to be quite different) is also not uncommon. He too had himself seen many ticks during his present tour. (4) The fever curve which rose slowly and ended by lysis after lasting for 21 days was somewhat longer than the extremes of 10 to 19 days given by Megaw, but the early and latter days of fever were very slight, and the days on which the maximum temperature was 100°F. or above were only 15. The remittent type of temperature was more typical. (5) The copious and conspicuous rose-red macules distributed all over the body but especially on the face, hands and feet, disappearing on pressure, erupting about the third day, turning at first darker red and then coppery brown and, finally, fading with the fall of the temperature to dull reddish stains, were distinctive. Very few spots were petechial. (6) The suffused eyes, throat and face were as usual. (7) The acute muscular and peri-articular pains and especially the backache were typical symptoms as in the Saugor (C. P.) cases observed by Shettle (Megaw, 1925), in which the fever also lasted up to 20 days, with daily remissions. (8) The great restlessness and the insomnia was also characteristic. (9) The spleen was definitely but only slightly enlarged as is often the case whilst the blood showed a slight leucocytosis (1,000) without any characteristic count. (10) Constipation. The only missing links, to render the diagnostic evidence fully complete, were (1) that of a tick having bitten the patient a few days previous to his attack and (2) evidence of the locality being definitely infected with endemic

tick typhus, though the evidence of a former case from this area makes it presumptive. The haematological findings and the immunological findings were also in harmony with tick typhus.

Differential clinical diagnosis of the rash and fever

1. *From mosquito-dengue.*—As noted above dengue was considered at first the probable diagnosis but the continuation of the fever beyond 7 days, its gradual mode of onset and its termination by lysis, and the profuse distribution of the rash with the absence of a dengue epidemic negated this diagnosis.

2. *From measles.*—The rash in places was not unlike a measles rash but in measles the morbilliform eruption constantly appears about the brow and behind the ears at the hair line on the fourth day and disappears in three or four days. The fever lasts only seven days or so.

3. *From cerebrospinal fever.*—The febrile onset is usually sudden. The headache is often occipital with neck pains, stiffness and the presence of Kernig's sign. Vomiting is often frequent. The rose spots appear over the trunk and limbs during the first week. Leucocytosis is considerable (about 30,000) and lumbar puncture is distinctive.

4. *From louse typhus.*—Louse typhus, of which I have seen epidemics in Mesopotamia and on the N.W. Frontier, is a far more serious disease, in which severe toxæmia with the presence of nervous symptoms, i.e., the blunting of the mental faculties with the great muscular prostration of the 'typhoid state' (resembling a drunken-alcoholic), is marked from the onset. The prostration is early and pronounced even during the first two or three days of the disease as compared with the corresponding toxic 'typhoid state' often seen after some ten days in severe typhoid infection. Louse typhus is also a more acute disease typically with a sudden onset and a sudden termination by crisis after some 14 days of fever. The mortality in louse typhus is high (about 15 per cent), in tick typhus it is low (5 per cent or below). Moreover epidemiologically louse typhus is a disease of dirt, famine and overcrowding, is readily conveyed from person to person and occurs in epidemics at the height of the cold weather. Attendants are readily infected. The rash appears very constantly on the fifth day, and is less conspicuous, with the palms, soles and face usually unaffected. Megaw states that the staining at the site of the spots clears rapidly and does not last for several weeks as with tick typhus.

5. *From mite typhus.*—There was no local sore or ulcer, with enlarged secondary glands indicating a bite.

6. *From typhoid fever.*—Clinically, if the case had been one of typhoid or of paratyphoid infection then the infection could only have been a mild one because of the absence of toxæmia, together with a remittent-intermittent type of temperature coupled with constipation rather than diarrhoea. But the profuse rash appearing on the third day was quite unlike typhoid and could only be explained by the coexistence of a second disease. Moreover, instead of leucopenia the total white count showed a feeble leucocytosis. Blood and clot cultures for *B. typhosus* were negative. The urine which had been cultured on the 3rd November and between the 7th and 22nd November on nine separate occasions remained sterile to *B. typhosus*. The stools also had been thrice negative to *B. typhosus*. The culture on the 7th, 22nd and 24th November. The agglutination reaction which rose from presumably 1/50 positive to 1/833 positive on the 21st day was the one evidence for *B. typhosus* infection (*vide infra*). Apart from the clinical and bacteriological evidence such a rise would have been regarded as diagnostic.

7. *Secondary syphilide.*—The patient had obviously not been exposed to conscious specific infection, nor were his wife (her Wassermann reaction was negative) or children affected. Nor were local signs of an old

or of a recent chancre present. Nor were there any signs of a secondary specific lymphadenitis. The 21 days' febrile curve was unlike the slight evening rise sometimes seen in secondary syphilis. Moreover the fact that the rash appeared on the second or third day of the disease and disappeared with the fall of the fever indicated that it was caused by the active infection from which the patient was suffering.

8. *Sweat rash*.—The patient's skin was dry. There was no musty smell of sweat. No sudamina were present. The distribution was not mainly in those areas which sweated most, e.g., the rash affected the hands, feet and face very obviously.

9. *Prickly heat*.—The body rash was not unlike prickly heat but was associated with a very definite febrile illness and did not come on in the hot season.

III. THE IMMUNE RESPONSES DEMONSTRATED IN THIS CASE AND BY THE TYPHUS FEVER GROUP AS A WHOLE

The antibody reactions demonstrated in the case described above were protean and curious. The clinical diagnosis of the case was rendered of increased scientific interest, if not of temporary perplexity, by the positive Wassermann, the positive Widal in high dilution, the positive Wilson-Weil-Felix reaction also in high dilution, and the high opsonic index which were successively demonstrated. Moreover these usually specific reactions were not due to a specific immune response to an infection with their homologous antigens. The possibility of syphilitic and of typhoid infection were for instance definitely excluded. Such heterologous immune response has however come to be recognized as a characteristic of typhus serum and more especially against the proteus group of organisms. But this heterologous response of typhus serum is by no means restricted to the proteus group, for a positive Wassermann or a positive Widal is also well recognized as a possible fallacy in dealing with typhus serum. Indeed, the presence of this non-specific and easily demonstrable quality in typhus serum no doubt

1. *The Wassermann reaction*.—The following table shows the patient's Wassermann reaction results:

Date blood taken	31st Oct.	7th Nov.	14th Nov.	22nd Nov.	7th Dec.
Day of disease.	14	21	28	36	45
W.R. result	++±	++—	—	—	—

In the discussion under syphilis in the differential diagnosis of this case, the clinical reasons why syphilis could be definitely excluded in this patient were noted. The fact that the positive Wassermann cleared completely within seven days of the temperature becoming normal without antisyphilitic treatment indicated that, serologically too, the temporary positive Wassermann was not due to syphilitic infection.

It is indeed accepted that in louse typhus the Wassermann reaction is almost always positive before the crisis, but becomes once again negative during convalescence [Bauer (Price, 1933), and Taylor (1925)]. Negative Wassermann reaction reports in typhus may be due to the fact that the serum was taken after the temperature had reached normal.

2. *The Widal reaction*.—The patient was inoculated five years ago at the same time as his wife. Her residual agglutinins in November 1934 were *B. typhosus* 1/50, *B. para A* 1/50, *B. para B* 1/25. In the following table 'M.C.' stands for Medical College and 'C.R.I.' stands for the Central Research Institute, Kasauli. The titre noted are the positive end-points found. In the Medical College Laboratory agglutinable suspensions made from Kasauli strains were solely used for this series of typhoid tests except from 24th November when Oxford suspensions were also put up.

explains the ease with which investigators have shown a positive agglutination to the several organisms which they have at one time or another proclaimed as being the causative germ of typhus infection. We are led indeed to conclude that the typhus toxin has this rare characteristic, namely that it stimulates widely and indiscriminately, and non-specifically, those tissues in the body which are usually concerned with the production of specific antibodies. Thus we can formulate a working hypothesis of the otherwise strange reactions which are found in practice in dealing with typhus fever serum. The serological reactions found in the case described above will now be detailed.

Clinically, the case was not one of typhoid fever. The bacteriological evidence also strongly supported this conclusion. And yet this remarkable rise in the typhoid agglutinins to 1/833 took place without a comparable rise in A and B agglutinins. Such a rise, except in typhus, would have been regarded as specific and as diagnostic of infection with *B. typhosus*. It is however of interest to note that the above rise to 1/833 on the 7th November affected typhoid H-agglutinins only that the Widal against typhoid O-agglutinins (an alcoholized suspension of a Kasauli culture being used) on this date and again on the 7th and on 20th December proved entirely negative.

It is well recognized that the Widal may be positive in typhus infection. Wilson in Muir and Ritchie (1932) originally noted this positive reaction. So also Megaw (1930) and Manson (1929). And such false positives have been the cause in the past of tick typhus cases being diagnosed as typhoid infections.

3. *The Wilson-Weil-Felix reaction.*—The following table sets out the patient's results. The titre on 31st October and 17th November was not end-point. One unexplained peculiarity about this reaction is its dependence on O antigen, wherefore formalized or phenol suspensions should not be used, and living suspensions, from a reliable strain, should be incubated with the patient's serum at 31°C. and not at 55°C. Neglect of these precautions have produced anomalous results.

Wilson-Weil-Felix reaction

Date blood taken.	31st Oct.	7th Nov.	10th Nov.	24th Nov.		7th Dec.			20th Dec.		
Day of disease	14	21	24	38		45			58

Proteus X 19	1/250	1/250	1/2,500	1/1,250	1/2,500	1/500	1/250	1/1,000	1/250	1/250	1/500
Proteus (K)	1/50	..	1/25	1/25	1/25	1/50	..	0	1/50	..	1/25
Proteus 2	1/25	1/50	0	1/50	..	0	1/50	..	0

Our patient therefore showed a very marked reaction to proteus X 19 which reached 1/25,000 between the 24th and 31st days. In louse typhus the Wilson-Weil-Felix reaction is generally recognized as being very reliable.* But the agglutination of *B. proteus* organisms with sera of the various varieties of typhus cases throughout the world have shown most anomalous results. The rule of thumb is that agglutination to X 19 is usually positive in high dilutions to louse typhus. In mite typhus it is negative whilst in tick typhus it may be positive.

Though in tick typhus the Wilson-Weil-Felix reaction has usually been reported negative yet in some outbreaks and cases, as in that reported above, it has been found positive. The Central Research Institute, Kasauli, however had several tick typhus cases in 1934 from the Simla Hills, most of which agglutinate Kingsbury strains, but some show a very high titre against X 19. One case amongst their own European staff showed a positive X 19 of 1/10,000. Thus this reaction cannot be relied upon as a point of distinction between louse, tick and mite typhus, in spite of the dogmatic claims that are at times made. For instance one famous textbook states 'The rural type of Malay typhus is negative to X 19, but positive to the Kingsbury strain, whilst in Indian tick typhus, neither the Kingsbury strain nor the original X 19 is agglutinated' (Muir and Ritchie, 1932). In actual fact, the Weil-Felix reaction is not really important in practical diagnosis, for the diagnosis is usually clear before the reaction can be carried out under proper conditions and becomes positive.

* The typhus commission found that in louse typhus reactions of 1/100 are almost diagnostic but in many cases positive reactions of 1/1,000 to 1/10,000 existed by the 14th day. The reaction appears about the 4th or 5th day in 50 per cent of cases, attains its height during the second week (when practically all cases are positive) and returns to negative in from six weeks to three months after the onset of the illness. Control reactions in other diseases do not exceed 1/50.

4. *The opsonic index.*—On the 10th November, i.e., on the 24th day of the disease and five days after the patient's temperature had reached and remained at normal, his blood serum showed an opsonic index of 4.6 to *Staphylococcus aureus*. On the 20th December, this had fallen to 1.25.

5. *Other agglutination reactions, etc.*—Agglutination reactions to *B. abortus* and to *B. coli communis* were negative on the 10th December, also to *M. melitensis* on 7th and again on 20th December. On the 7th December the agglutinins to *B. coli communis* and to *B. coli communior* were both 1/25 positive. The aldehyde test was also negative on this date. Olitsky in 1921 stated that antibodies are formed in the blood of typhus patients not only against the proteus group but sometimes against *B. pyocyaneus*, *melitensis* and
